Contents

List of Contributors xi

Foreword xix

Preface to the fifth edition xxi

List of Abbreviations xxiii

Section I: Evaluation of the Pediatric Urologic Patient

1. History and physical examination of the child 3
   T Ernesto Figueroa
2. Laboratory assessment of the pediatric urologic patient 11
   Paul F Austin and Erica J Traxel
3. Fetal urology and prenatal diagnosis 19
   David FM Thomas
4. Office ultrasonography 35
   Dennis B Liu and Max Maizels
5. Pediatric renal nuclear medicine 53
   Martin Charron
6. Prenatal and postnatal urologic emergencies 61
   Patrick H McKenna and Fernando A Ferrer
7. Urinary tract infections in children 103
   Hans G Pohl and H Gil Rushton
8. Fungal, parasitic, and other inflammatory diseases of the genitourinary tract 167
   William A Kennedy II
9. Pain management for the pediatric urologic patient 183
   Stephen C Brown and Patricia A McGrath
10. Office pediatric urology 199
    Patrick C Cartwright, Timothy A Masterson, and Brent W Snow
11. Principles of minimally invasive surgery 215
    Walid Farhat and Pasquale Casale
12. Pediatric fluid management 223
    James M Robertson
13. Embryology of the genitourinary tract 231
    Steven E Lerman, Irene M McAleer, and George W Kaplan

Section II: The Adrenal

14. Adrenal or suprarenal gland development 237
    Steven E Lerman, Irene M McAleer, and George W Kaplan

15. Radiologic assessment of the adrenal 241
Kourosh Afshar, Douglas H Jamieson, and Andrew E MacNeily

16. Adrenal tumors and functional consequences 249
Julie Franc-Guimond and Anne-Marie Houle

17. Surgery of the adrenal 259
Stephen Boorjian, Michael Schwartz, and Dix P Poppas

Section III: The Kidney

18. Basic science of the kidney 271
John C Thomas and John C Pope IV

19. Renal vasculature and kidney 283
Steven E Lerman, Irene M McAleer, and George W Kaplan

20. Renal anomalies 293
Michael L Ritchey and Susan John

21. Fetal and neonatal renal function 313
Billy S Arant Jr

22. Cystic kidney disease 327
Larry Greenbaum

23. Acute renal failure 357
Lawrence Copelovitch, Bernard S Kaplan, and Kevin EC Meyers

24. Renal transplantation 367
Nafisa Dharamsi, Curtis Sheldon, and Jens Goebel

25. Renal calculus disease 387
Pramod P Reddy and Eugene Minevich

26. Endourology for stone disease 401
Aseem Shukla and Michael Erhard

27. Renal parenchymal imaging in children 421
J Michael Zerin

28. Assessment of renal obstructive disorders: ultrasound, nuclear medicine, and magnetic resonance imaging 447
James Elmore and Andrew J Kirsch

29. Assessment of renal obstructive disorders: urodynamics of the upper tract 461
Leo CT Fung (deceased) and Ɣegappan Lakshmanan

30. Ureteropelvic junction obstruction and multicystic dysplastic kidney: surgical management 479
Michael C Carr

31. Laparoscopic nephrectomy and pyeloplasty 487
Alaa El-Ghoneimi

32. Wilms' tumor 497
Michael L Ritchey and Fernando A Ferrer

33. Surgical approaches for renal tumors 519
Joao Luiz Pippi Salle and Roman Jednak

34. Upper urinary tract trauma 529
Douglas A Husmann

Section IV: The Ureter

35. The ureter 541
Cem Akbal and Martin Kaefer

36. Ureteral development 553
Steven E Lerman, Irene M McAleer, and George W Kaplan

37. The imaging of reflux and ureteral disease 555
Jeanne S Chow and David A Diamond

38. Ureteral anomalies and their surgical management 571
Christopher S Cooper

39. Megaureter 577
David B Joseph

40. Ureteral duplication anomalies: ectopic ureters and ureteroceles 593
Michael A Keating

41. Laparoscopic management of duplication anomalies 649
Alberto Lais and Craig A Peters

42. Vesicoureteral reflux: anatomic and functional basis of etiology 655
John M Park

43. Non-surgical management of vesicoureteral reflux 663
Jack S Elder

44. Surgery for vesicoureteral reflux 673
John W Brock III and Romano T DeMarco

45. Minimally invasive approaches to correct vesicoureteral reflux 687
Patrick Cartwright and Brent W Snow

46. Injection therapy for vesicoureteral reflux 691
Anthony A Caldamone

Section V: The Bladder and Prostate

47. Basic science of the urinary bladder 713
Armando J Lorenzo and Darius J Bägli

48. Basic science of prostatic development 723
Ellen Shapiro and Hongying Huang

49. Embryology of the anterior abdominal wall, bladder, and proximal urethra 733
Steven E Lerman, Irene M McAleer, and George W Kaplan

50. Radiologic assessment of bladder disorders 739
Douglas E Coplen

51. Urodynamics of the lower and upper urinary tract 747
William E Kaplan

52. Neurologic control of storage and voiding 765
Julian Wan and John M Park

53. Neurogenic voiding dysfunction and non-surgical management 781
Stuart B Bauer

54. Diurnal and nocturnal enuresis 819
Mark Horowitz and Rosalia Misseri

55. Operations for the weak bladder outlet 841
Anthony J Casale

56. Bladder augmentation: current and future techniques 871
Bradley P Kropp and Earl Y Cheng

57. Urinary diversion 911
Mark P Cain, Peter D Metcalfe, and Richard C Rink

58. The Malone antegrade continence enema (MACE) 947
Martin A Koyle and Padraig SJ Malone

59. Minimally invasive approaches to lower urinary tract reconstruction 957
Christina Kim and Steven G Docimo

60. Genitourinary rhabdomyosarcoma and other bladder tumors 969
Paul A Merguerian, Lisa Cartwright, and Antoine E Khoury

61. Exstrophy and epispadias 999
Linda A Baker and Richard W Grady

62. Unusual conditions of the bladder, including bladder trauma, urachal anomalies, and bladder diverticula 1047
Marc Cendron

63. Posterior urethral values 1059
Stephen A Zderic and Douglas A Canning

64. Prune belly syndrome 1081
R Guy Hudson and Steven J Skoog

Section VI: Urethra, External Genitalia, and Retroperitoneum

65. Basic science of the genitalia 1117
Laurence S Baskin

66. Basic science of the testis 1127
Julia Spencer Barthold

67. Gonads, genital ducts, and genitalia 1139
Steven E Lerman, Irene M McAleer, and George W Kaplan

68. Intersex 1147
Hsi-Yang Wu and Howard M Snyder III

69. Anorectal malformation and cloaca 1161
Curtis A Sheldon and William R DeFoor Jr

70. Surgery for intersex disorders and urogenital sinus 1187
Mark C Adams and Romano T DeMarco

71. Hypospadias 1205
Warren T Snodgrass, Aseem R Shukla, and Douglas A Canning

72. Abnormalities of the penis and scrotum 1239
Michael F MacDonald, Julie Spencer Barthold, and Evan J Kass

73. Hernia, hydroceles, testicular torsion, and varicocele 1271
Hiep T Nguyen

74. Cryptorchidism 1295
Thomas F Kolon

75. Surgical management of the undescended testis 1309
Israel Franco

76. Testicular tumors 1329
Jonathan H Ross

77. Tumors of the retroperitoneum 1339
Gordon A McLorie and Darius J Bägli

78. Tissue engineering for pediatric urology 1363
Anthony Atala

Index 1375

Foreword

It is hard to believe that the time has come for a fifth edition of *Clinical Pediatric Urology*. It is even harder to realize that it has been over 30 years since our first edition was conceived and delivered. The history leading up to the first edition might be of some interest. Both Kelalis at the Mayo Clinic and King at Children's Memorial Hospital in Chicago had contracts to write or edit books. However, there was so much going on at that time in this new, young field of pediatric urology, clinically and academically, that there was little time for either to get the job done. It was a fertile, uncultivated field and a very exciting time. New discoveries and advances were being made daily. Kelalis and King ultimately joined forces, enlisting Belman, who was working with King in Chicago, as an author and associate editor, as well as most of the few other pediatric urologists in the field at the time to write chapters. The first edition was well received, with nearly 4000 of the two-volume text sold. The sales exceeded that of the edition of *Campbell's Urology* published about the same time.

The book was meant to continue in the tradition of Meridith Campbell, who had published a two-volume text entitled *Pediatric Urology* in 1937 and the original *Clinical Pediatric Urology* in 1951. The controversies of the day – such as the significance of vesicoureteral reflux, particularly in the absence of infection, the role of the urethra and bladder neck as causative factors of urinary tract infection and reflux, management of the child with neuropathology, and innovative surgical techniques – were all addressed in both Campbell texts as well as in our first edition of 1976. Most of these same questions are addressed in this current edition, although at a much more sophisticated and scientific level. Others have been resolved and the progress that has been made, particularly regarding the surgical treatment of hypospadias, bladder exstrophy and endoscopic treatment of reflux as well as other problems, as reported in this edition, is truly amazing.

Each of the editions that followed the first was meant to build on the previous one. Different authors were often chosen in following editions to keep the information 'fresh.' Of course, this became easier as the field grew and more experts became available. Often portions of previous chapters were incorporated to build upon by new authors and to offer historical perspective and depth. We continue to appreciate all the efforts by those who contributed to the first four editions.

This is the first edition in which none of the previous editors participated. This is a good thing, as it offers the opportunity to consider totally new perspectives of our growing field. We hope that the previous editions were of use to the current editors and authors and wish them well with their endeavor. We know from first-hand experience that 'doing a book' is a huge undertaking and often a frustrating experience. We wish them well. Our only regret is that Panos Kelalis is not here to see the fruits of his labors and take pride that his 'baby' has grown into this mature body.

Lowell R King
Professor Emeritus of Urology
Duke University School of Medicine

Albuquerque, New Mexico

A Barry Belman
Professor and Chairman Emeritus
Department of Urology
Children's National Medical Center
Washington, DC

Preface to the fifth edition

The textbook *Clinical Pediatric Urology*, known affectionately as 'Kelalis, King and Belman', has been the primary resource for pediatric urologists, residents and fellows for 30 years. We are honored to have the opportunity to edit the fifth edition. To commemorate the origins of this book, the title has been changed to *The Kelalis–King–Belman Textbook of Clinical Pediatric Urology*. We are fortunate to have the assistance of Barry Belman and Lowell King, who have supplied a Foreword to this text. Their contributions, along with Steven Kramer, who served as co-editor of the fourth edition, and of course the late Panayotis Kelalis cannot be overestimated. We are indebted to their vision, and the strong foundation they created, and upon which the current text is built.

The specialty of pediatric urology continues to grow and change rapidly. In the United States, pediatric urologists will soon have the opportunity to earn a Certificate of Added Qualification in pediatric urology, in addition to the Urology Boards. More pediatric urology is being done by full-time specialists, and less by general urologists. Areas of great controversy in the past, such as the utility of laparoscopy in pediatric urology, are now better defined, whereas areas for which we thought we had the answers, such as the management of vesicoureteral reflux, seem to be completely up in the air. We are on the verge of an era of translation of basic science discoveries to clinical therapies – most notably in pharmacotherapy and tissue engineering. We hope that this book will enlighten in all of these areas, and supply guidance where it is needed most.

We reorganized the textbook, starting with chapters of general interest, and then proceeding through each of the systems or anatomical areas of interest to urologists. Within each section, we have tried to incorporate a basic science chapter. Understanding that this is a clinical text, these authors have been tasked with enlightening the reader with those basic science efforts that are likely to impact clinical care now or in the future. The embryology and radiology chapters have been distributed throughout the book, according to system. Finally, minimally invasive surgery is no longer sequestered in a chapter of its own, but is incorporated in each section of the book. We are indebted to our returning authors, who graciously accepted and enhanced our new format, and to our many new authors who have infused the text with their energetic contributions.

As always, this is intended as a reference work, but not necessarily the last word. We have tried to present controversy where it exists, but in the end all recommendations are made based on the experience and best belief of the authors. The authors have been chosen in every case for their expertise, experience and rationality. Although we, as editors, may not have agreed with everything our authors have stated, we consider each of them a master in their area, and have tried to minimize our influence on their message.

We are especially indebted to our publisher, Alan Burgess of Informa Healthcare, without whose trust and guidance this work would not have begun; and his development editor Kelly Cornish, and to our production editor Cathy Hambly without whose hard work it would not have been finished.

Abbreviations

α_1-ANRB	α_1-adrenergic receptor-blocker
α-SMA	α-smooth muscle actin
AAP	American Academy of Pediatrics
ABL	allowable blood loss
ABU	asymptomatic bacteriuria
ACE	angiotensin-converting enzyme
ACEIs	angiotensin-converting enzyme inhibitors
ACKD	acquired cystic kidney disease
ACTH	adrenocorticotropic hormone
ADH	antidiuretic hormone
ADPKD	autosomal dominant polycystic kidney disease
AFP	alpha-fetoprotein
AGN	acute glomerulonephritis
AGT	alanine-glyoxylate aminotransferase
AIDS	acquired immunodeficiency syndrome
AIS	androgen insensitivity syndrome
ALPP	abdominal leak point pressure
ALT	alanine aminotransferase
AMD	dactinimycin
ANA	antinuclear antibodies
ANCA	antineutrophil cytoplasmic autoantibodies
ANGII	angiotensin II
AP	anteroposterior
APA	aldosterone-producing adenoma
APD	anteroposterior diameter
AR	androgen receptor
ARB	arterial blood gases
ARBs	angiotensin receptor blockers
ARF	acute renal failure
ARMS	alveolar rhabdomyosarcoma
ARMs	anorectal malformations
ARPKD	autosomal recessive polycystic kidney disease
ASO	antistreptolysin O (titer)
AST	aspartate aminotransferase
AT1, AT2	angiotensin type 1 and 2 receptors
ATN	acute tubular necrosis
ATP	adenosine triphosphate
AUA	American Urological Association
AVM	arteriovenous malformation
BAH	bilateral adrenal hyperplasia
BAMA	bladder acellular matrix allografts
BAMG	bladder acellular matrix grafts
BAPS	British Association of Paediatric Surgeons
BC	bladder capacity
bFGF	basic fibroblast growth factor
BLE	bladder epithelium
BMP	bone morphogenetic protein
BNR	bladder neck reconstruction
BPH	benign prostatic hyperplasia
BRMS	botryoid rhabdomyosarcoma
bSMCs	bladder smooth muscle cells
BT	bleeding time
BUN	blood urea nitrogen
BWS	Beckwith–Wiedemann syndrome
BWT	bilateral Wilms' tumor
BXO	balanitis xerotica obliterans
C&S	culture and sensitivity
CA	cyproterone acetate
CAH	congenital adrenal hyperplasia
CAIS	complete androgen insensitivity (syndrome)
CAKUT	congenital abnormalities of the kidney and urinary tract
CAM	complementary/alternative therapies
CaMK	calcium–calmodulin dependent protein kinase
cAMP	cyclic adenosine monophosphate
CAN	chronic allograft nephropathy
CAPD	continuous ambulatory peritoneal dialysis
caspases	cysteinyl aspartate-specific proteinases
CBC	complete blood count
CCSK	clear cell carcinoma of the kidney
CDT	contralateral descended testes
CEC	central echogenic complex
CFU	colon-forming unit
cGMP	cyclic guanosine monophosphate
CGRP	calcitonin gene-related peptide
CI	calcineurin inhibitor
CIC	clean intermittent catheterization
CMC	corticomedullary crossover
CMN	congenital mesoblastic nephroma
CMs	cloacal malformations
CMV	cytomegalovirus
COX	cyclooxygenase
CPRE	complete primary repair for exstrophy
CPT	Current Procedural Terminology

CRF	chronic renal failure
CRH	corticotropin-releasing hormone
CRI	chronic renal insufficiency
CRP	C-reactive protein
CRRT	continuous renal replacement therapy
CSF	cerebrospinal fluid
CT	computed tomography
CURs	continent urinary reservoirs
CV	cardiovascular
CVA	costovertebral angle
CVP	central venous pressure
CWS	Cooperative Soft Tissue Sarcoma Study Group
DBP	dibutyl phthalate
DES	diethylstilbestrol
DES	dysfunctional elimination syndrome
DG	diacylglycerol
DGDH	D-glycerate dehydrogenase
DHEA	dehydroepiandrosterone
DHEAS	dehydroepiandrosterone sulfate
DHMEQ	dehydroxymethylepoxyquinomicin
DHT	dihydrotestosterone
DI	detrusor instability
DI	diabetes insipidus
DM	diabetes mellitus
DMSA	dimercaptosuccinic acid
DOC	deoxycorticosterone
DOX	doxorubicin
DRF	differential renal function
DRG	dorsal root ganglion
DRS	diuretic renal scintigraphy
DSD	detrusor–sphincter dyssynergia
DTPA	diethylenetriamine pentaacetic acid
DVSS	Dysfunctional Voiding Scoring System
DVSS	dysfunctional voiding system score questionnaire
Dx/HA	dextranomer/hyaluronic acid copolymer
EABV	effective arterial blood volume
EB	elementary body
EBV	Epstein–Barr virus
EBV	estimated blood volume
ECF	extracellular fluid
ECG	electrocardiogram
ECM	extracellular matrix
ECMO	extracorporeal membrane oxygenation
EDs	ejaculatory ducts
EFS	event-free survival
EGF	epidermal growth factor
EHL	electrohydraulic lithotripsy
ELISA	enzyme-linked immunosorbent assay
EM	ectomesenchymoma
EMG	electromyography (electromyogram)
EMT	epithelial–mesenchymal transition
EPO	erythropoietin
ER	estrogen receptor
ER	estrogen receptor
ERα	estrogen receptor α
ERβ	estrogen receptor β
ERK	extracellular signal-regulated kinase
ERKOα	estrogen receptor α knockout mouse
ERKOβ	estrogen receptor β knockout mouse
ERMS	embryonal rhabdomyosarcoma
ESR	erythrocyte sedimentation rate
ESRD	end-stage renal disease
ESWL	extracorporeal shock wave lithotripsy
EU	excretory urography
FDA	Food and Drug Administration
FDG	fluorodeoxyglucose
FENa	fractional excretion of sodium
FFP	fresh frozen plasma
FGF-2	fibroblast growth factor-2
FH	favorable histology
FISH	fluorescent in-situ hybridization
FJHN	familial juvenile hyperuricemic nephropathy
FKHR	fork head in rhabdomyosarcoma
Flk-1	fetal liver kinase-1
FNA	fine-needle aspiration
Fr	French
FSH	follicle-stimulating hormone
G6PD	glucose-6-phosphate dehydrogenase
GABA	γ-aminobutyric acid
GBM	glomerular basement membrane
GCKD	glomerulocystic kidney disease
GCSF	granulocyte colony-stimulating factor
GDNF	glial-cell-line-derived neurotrophic factor
GFN	genitofemoral nerve
GFR	glomerular filtration rate
GI	gastrointestinal
GnRH	gonadotropin-releasing hormone
GRA	glucocorticoid-remediable aldosteroniclm
GU	genitourinary
HBEGF	heparin-binding EGF-like growth factor
Hbf	minimal allowable hemoglobin
Hbi	initial hemoglobin
hCG	human chorionic gonadotropin
HDS	hematuria–dysuria syndrome
HIF	hypoxia inducible factor
HIV	human immunodeficiency virus

HLA	human leukocyte antigen
HNF-1β	hepatocyte nuclear factor –1β
HPA	hypothalamic–pituitary–adrenal (axis)
HPF	hepatocyte growth factor
HPF	high-power field
HPRT	hyperfractionated radiation therapy
HPRT	hypoxanthine–guanine phosphoribosyl transferase
HSK	horseshoe kidney
HUS	hemolytic uremic syndrome
ICAM-1	intercellular adhesion molecule 1
ICF	intracellular fluid
ICR	International Classification of Rhabdomyosarcoma
ICSI	intracytoplasmic sperm injection
ICU	intensive care unit
IE	ifosfamide + etoposide
IGF-1	insulin-like growth factor-1
IGF-1R	insulin-like growth factor-1 receptor
IGFBP-6	insulin-like growth factor binding protein-6
IL	interleukin (IL-2)
ILNR	intralobular nephrogenic rest
IMC	intermittent catheterization
iNOS	inducible nitric oxide synthase
INR	international normalized ratio
IOUS	in-office ultrasonography
IP_3	inositol 1,4,5-triphosphate
IRS IV	Intergroup Rhabdomyosarcoma Study IV
IRSG	Intergroup Rhabdomyosarcoma Group
IV	intravenous
IVC	inferior vena cava
IVP	intravenous pyelography (pyelogram)
IVU	intravenous urography
IZ	inner submucosal zone
JCAHO	Joint Commission on Accreditation of Health Care Organizations
JNK	c-Jun N-terminal kinase
KUB	kidney, ureter, and bladder (abdominal X-ray)
LBAA	laparoscopic bladder autoaugmentation
LDL	lactate dehydrogenase
LH	luteinizing hormone
LHRH	luteinizing hormone- releasing hormone
LIF	leukemia inhibitory factor
LOH	loss of heterozygosity
LPP	leak point pressure
LUTS	lower urinary tract symptoms
MACE	Malone antegrade continence enema
MAG3	mercaptoacetyltriglycine
MAPK	mitogen-activated protein kinase
MCDK	multicystic dysplastic kidney
MCKD	medullary cystic kidney disease
MCP-1	monocyte chemoattractant protein-1
MCU	mictating cystourethrogram
MDCT	multidetector computed tomography
MDK	multicystic dysplastic kidney
MDs	müllerian ducts
MEN 1	multiple endocrine neoplasia type I
MET	mesenchymal–epithelial transition
MIBG	metaiodobenzylguanidine
MIP	maximum intensity projection
MIS	müllerian inhibiting substance
MMC	myelomeningocele
MMK	Marshall–Marchetti–Krantz (procedure)
MMP	matrix metalloproteinase
MNE	monosymptomatic nocturnal enuresis
MNU	Mitrofanoff neourethra
MODY	maturity-onset diabetes of the young
MRA	magnetic resonance angiography
MRI	magnetic resonance imaging
MRU	magnetic resonance urography
MSK	medullary sponge kidney
MSRE	modern staged repair for exstrophy
MVA	motor vehicle accident
MVP	mitral valve prolapse
NAG	*N*-acetyl-β-D-glucosamidase
NE	nocturnal enuresis
NF-κB	nuclear factor-κB
NGF	nerve growth factor
NICU	neonatal intensive care unit
NO	nitric oxide
NPH	nephronophthisis
NSAIDs	non-steroidal anti-inflammatory drugs
NWTSG	National Wilms' Tumor Study Group
OS	overall survival
OTFC	oral transmucosal fentanyl citrate
PAH	para-aminohippurate
PAI-1	plasminogen activator-1
PAIS	partial androgen insensitivity
PBND	primary bladder neck dysfunction
PCA	patient-controlled analgesia
PCAP	pituitary adenylate cyclase-activating peptide
PDE	phosphodiesterase
PDGF-BB	platelet-derived growth factor-BB
PEC	percutaneous endoscopic colostomy
PEG	percutaneous endoscopic gastrostomy
PET	positron emission tomography

PFS	progression-free survival
PI3K	phosphatidylinositol 3-kinase
PIN	prostatic intraepithelial neoplasia
PLAP	placental alkaline phosphatase
PLNR	perilobular nephrogenic rest
PMC	pontine micturation center
PMTs	pseudosarcomatous myofibroblastic tumors
PNE	primary nocturnal enuresis
PNMC	Pediatric Nuclear Medicine Council
POG	Pediatric Oncology Group
POMC	pro-opiomelanocortin
PRA	plasma renin activity
PRBCs	packed red blood cells
PRE	prostatic epithelium
PSAP	posterior sagittal anoplasty
PSARP	posterior sagittal anorectoplasty
PSARUVP	posterior sagittal anorectal urethrovaginoplasty
PSPV	pressure-specific bladder volume
PT	prothrombin time
PTFE	polytetrafluoroethylene
PTH	parathyroid hormone
PTLD	post-transplant lymphoproliferative disorder
PTT	partial prothrombin time
PUJ	pelviureteral junction
PUV	posterior urethral valves
PV	processus vaginalis
PVR	postvoid residual urine
PZ	peripheral zone
QOLI	quality of life improvement
RAS	renin–angiotensin system
RB	reticulate body
RBCs	red blood cells
RBCs/HPF	red blood cells per high-power field
RBF	renal blood flow
RCC	renal cell carcinoma
RI	resistive index
RMS	rhabdomyosarcoma
RNC	radionuclide cystography
ROC	receiver operating characteristic
ROS	reactive oxygen species
RPGN	rapidly progressive glomerulonephritis
RR	relative risk
RTA	renal tubular acidosis
RTK	rhabdoid tumor of the kidney
RT-PCR	reverse transcription polymerase chain reaction
RTT	renal transit time
RUP	retrograde ureteropyelography
RVR	renal vascular resistance
RVT	renal venous thrombosis
SBE	subacute bacterial endocarditis
SERP	sonographically evident renal pyelectasis
SFU	Society for Fecal Urology
SG	specific gravity
SIADH	syndrome of inappropriate antidiuretic hormone
SIOP	International Society of Pediatric Oncology
SIS	small intestinal submucosa
SKM	skeletal muscle
SM	smooth muscle
SMN	second malignant neoplasm
SNARE	soluble N-methylmaleimide-sensitive factor attachment protein (SNAP) receptor
SNP	single nucleotide polymorphisms
SPA	suprapubic aspiration
SPECT	single-photon emission computed tomography
SPN	sacral parasympathetic nucleus
SQM	squamous metaplasia
SRC	steroid receptor coactivator
SRY	sex-determining region of the Y chromosome
SS	supersaturation
SSRIs	selective serotonin uptake inhibitors
StAR	steroid acute reaction protein
STING	subtrigonal injection
STS	Soft Tissue Sarcoma
SVM	seminal vesicle mesenchyme
TBW	total body water
TCC	transitional cell carcinoma
TF	transdermal fentanyl
Tfm	testicular feminization (syndrome)
TGF-β_1	transforming growth factor-β_1
TIMPs	tissue inhibitors of MMPs (matrix metalloproteinases)
TINU	tubulointerstitial nephritis and uveitis
TLR	toll-like receptor (TLR-2, TLR-4)
TLV	total lung volume
TNF-α	tumor necrosis factor-α
TS	tuberous sclerosis
TTP	thrombotic thrombocytic purpura
UA	urinalysis
UAH	unilateral adrenal hyperplasia
UDT	undescended testes
UGE	urogenital epithelium
UGM	urogenital mesenchyme
UGS	urogenital sinus

UKCCSG	United Kingdom Children's Cancer Study Group
UMC	undifferentiated mesenchyme
UPJ	ureteropelvic junction
UPJO	ureteropelvic junction obstruction
URA	unilateral renal agenesis
URGMs	urogenital sinus malformations
US	ultrasound, ultrasonography
UTI	urinary tract infection
UVJ	ureterovesical junction
UVJO	ureterovesical junction obstruction
VA	vincristine + dactinomycin
VAC	vincristine + dactinomycin + cyclophosphamide
VCH	Vanderbilt Children's Hospital
VCR	vincristine
VCUG	voiding cystourethrography (cystourethrogram)
VEGF	vascular endothelial growth factor
VHL	von Hippel–Lindau (disease)
VIP	vasoactive intestinal peptide
VLPP	Valsalva leak point pressure
VM	vincristine + melphalan
VP	ventriculoperitoneal (e.g. VP shunt)
VUDS	videourodynamics
VUJ	vesicoureteral junction
VUR	vesicoureteral reflux
vWF	von Willebrand factor
vWFRCo	vWF ristocetin cofactor activity
WAGR	Wilms' tumor, aniridia, genitourinary, retardation
WBCs	white blood cells
WD	wolffian duct
WT	wild-type
XRT	radiation therapy
YDL	Young–Dees–Leadbetter (procedure)

Section I

Evaluation of the Pediatric Urologic Patient

History and physical examination of the child

1

T Ernesto Figueroa

> Although the perfect history has never been taken by any physician, his careful, sympathetic and discerning questions frequently yield information from the sick person which enlarges the doctor's horizon of knowledge and experience as well as presenting him with unexpected examples of the dramatic or bizarre.

The medical history

The path to caring for a patient and offering a solution to a medical condition commences with a well-taken and thorough medical history, and subsequent physical examination. These are the most basic of elements in medical care, and when properly conducted, allow for the understanding and appreciation of the medical condition, and the ability to initiate appropriate care for the patient. The extensive progress in medical technology has given the physician new tools for the diagnosis and treatment of most medical conditions; however, no technological advance can replace the sympathetic and discriminating ear of the physician, or the gentle and perceptive hand during the physical examination. In the diagnostic process, history accounts for 80% of the information, physical examination for 15%, and special investigations for 5%.[1] A thorough history is the clearly most enlightening component of the diagnostic process.[2]

The field of pediatrics presents a very different situation than the other branches of medicine in that the history is usually given by a second person instead of the patient, this being the mother, the father, other relatives, or a foster parent.[3] It is important to identify the person giving the history, and to clarify the relationship to the patient. As we first encounter the child and the parent, it is essential to introduce ourselves and offer our services to the patient and the family. The accompanying adult should be asked in a non-threatening way about his/her relationship to the patient. In an era of significant governmental regulatory oversight and the obligation to protect the patient's confidentiality and privacy, it is necessary to define the precise relationship to the patient early on in the interaction, and to determine who will be the recipient of the medical information related to the pediatric patient.[4] Current federal regulations establish limitations on the medical information that can be shared with individuals other than the patient, and there can be serious penalties for ignoring this federal directive. We should not assume that the accompanying adult has legal custody of the child.

Upon approaching an examination room, it is important to remember that small children will often move about the room, as the family waits for the physician. Prior to entering the room, the physician should first knock gently at the door to alert the parents to pick up the child who could be sitting behind the door, and then open the door cautiously. As we first encounter the child and accompanying adult, it is helpful to ask what the child likes to be called, and address the child in that manner. Also, it is beneficial to find an area of interest that will show patients that we care and are interested in them, such as asking what type of play they enjoy, offer a supportive commentary about their clothes, or inquire about their interests in sports or other activities. The child should feel that they are the primary interest of the interaction, and regardless of the age, the physician should look at the child and talk to him/her in words that the child can understand at various times during the encounter. A soft and courteous tone of voice and a sympathetic look are essential in developing a trusting relationship with the child, assuring the patient and the family that the physician is concerned about

his/her condition. Abrupt, pressing and hurried interfaces often have a profoundly negative effect on the initial, and subsequent, patient–physician interactions. The physician should convey a willingness to listen, and demonstrate empathetic understanding for the information being gathered.[2] If a young child is not receptive to the interaction and is disruptive during the history taking, it is helpful to seek distraction techniques such as a toy box, coloring books, formula or snacks, or removal from the examination room, to allow adequate history gathering. A comfortable environment can enhance communication.[3] In essence, it is important to convey to the parent the interest in the child as well as the illness.[5]

The pediatric urologic history should be tailored to the condition of the patient, with some conditions being rather evident, such as the healthy newborn with hypospadias or undescended testis, and thus requiring a more focused and limited approach to the history. Other conditions, such as combined diurnal and nocturnal enuresis in an older patient, are likely to require a more detailed and comprehensive assessment of the medical history. Thus, not every patient seen by a pediatric urologist will require an extensive medical history with a need to cover all of the items traditionally listed in the medical history of a child. However, the role of the pediatric urologist is to determine what key questions are necessary to formulate the most accurate description of the patient's genitourinary condition. Once the pediatric urologist has established the main reason for the visit or interaction with the patient, additional information is necessary to complete the history. The family should be questioned about possible associated genitourinary symptoms including flank pain, abdominal pain, dysuria, hematuria, incontinence, frequency and urgency, difficulty with urination, previous urologic surgery, and scrotal pain and swelling. Other symptoms such as malaise, fever, weight loss, constipation, vomiting, or body posturing should be reviewed as part of the history of the present illness. The past medical history should include information about the prenatal history of the patient and pregnancy of the mother, including any fetal assessment, and illnesses or medication to which the mother was exposed. Any current or previous medications should be listed, as well as allergic reactions to medications. A comprehensive developmental history is not crucial to the pediatric urologic history, though a general awareness about the patient's ability to reach developmental milestones is important. Serious previous medical conditions and operations need to be documented. In assessing the review of systems, particular attention should be given to the overall state and growth of the patient, the presence or absence of reactive airway disease, and a history of congenital cardiac malformations.

Genitourinary surgery is one of the common indications for subacute bacterial endocarditis (SBE) prophylaxis in patients with some types of congenital heart disease, and the child's cardiologist should specify the need for antibiotic use for these patients. Other important elements of the review of systems include recurrent abdominal pain, constipation, diarrhea, or vomiting, and any nervous system abnormalities such as seizure disorders or attention deficit disorder. Recurrent abdominal pain and vomiting may be a presentation of intermittent hydronephrosis in a child. The assessment of the family history is important for many pediatric urologic conditions, including vesicoureteral reflux, urinary tract infections, genital malformations including hypospadias, and voiding disorders and enuresis. Finally, if not already obtained during the initial interaction, an assessment of the social history should be completed, including the marital status of the parents, who cares for the children when the mother is employed, number of siblings, progress at school, recent stressful experiences such as moving or loss of a family member, and the type of interactions with other children.[3,5,6] All of this information may elicit a diagnostic path possibly unrelated to the initial complaint of the patient.

The gathering of medical information occurs in many scenarios in the field of pediatric urology. The interaction with an expectant mother with a prenatally detected urologic malformation is very different from the interaction with an acutely ill boy with scrotal pain. Just as the types of questions and data gathering need to be adjusted according to a given medical scenario, so does the documentation of that encounter. In the 1990s, the 'Documentation Guidelines for Evaluation and Management Services' were developed by Health Care Financing Administration (HCFA) and the American Medical Association, and since then, many variations of these guidelines have evolved. The guidelines, commonly referred to as the E/M service guidelines, were developed with the premise that medical interactions should provide specific documentation of the history, physical examination, and decision-making process, in order to be processed and reimbursed by Medicare. Each interaction, be it with a new or an established patient, is coded according to the number of items (bullets) covered during the interaction. Three broad categories are used (office visits, hospital visits, and consulta-

tions), and each of these categories is further subdivided according to a new or established interaction with a patient.[7–9] In the context of this chapter, it is necessary to mention this newer component of the medical history and physical examination, though it is not the intent of this chapter to expand on these complex and controversial coding guidelines.

The physical examination

An important component of the physical examination occurs while obtaining the medical history, and that is the observation of the patient and the relationship with the family. While listening to the family, the physician can assess the level of comfort of the child and his/her overall physical health, and anticipate the approach to the physical examination. Perusing the vital signs, including the weight, blood pressure, temperature and pulse, prior to examining the child may point to the need to focus on specific areas of the examination. An elevated blood pressure is often seen in the agitated child, or when the blood pressure cuff is too small for the child, although it may also be the result of renal disease. Selecting the appropriate blood pressure cuff size for the child is vital to obtaining reliable blood pressure readings.[2]

When the time comes for the examination, the child should be informed in simple terms that are understandable to him/her that an examination is to take place. With younger children, having the parents stand or sit next to them during the examination can help reduce the fear of the experience. Young children, less than 1 year of age, can occasionally be examined while they recline in their mother's lap. Every effort should be taken to minimize separation anxiety in these children, common in children younger than 3 years of age. Preschoolers, ages 4–6 years, fear the possibility of bodily injury and mutilation, possibly castration, so the genital examination usually produces significant anxiety in this age group. In older children, and adolescents, privacy is very important, and respecting that privacy during the examination is vital, by asking the family members to look aside or to step out of the room. Examination of the adolescent should always be handled with sensitivity to avoid unnecessary embarrassment and preserve the dignity of the patient.[10]

Prior to placing the hands on the patient, the examining physician should wash his/her hands, and repeat this routine, though fundamental, exercise at the end of the examination. A cold pair of hands can tense the patient unexpectedly. The physician owes to the patient the courtesy of a warm pair of hands during the examination.[10] Upon placing the patient on the examining table, the pediatric urologist can determine if the child will cooperate with the examination. If the child is cooperative, the examination should include an assessment of the configuration of the chest and abdomen, appearance of the breast tissue in both boys and girls, presence of axillary hair, palpation of all four quadrants of the abdomen for abdominal wall tension, masses, rigidity, guarding or tenderness, and the presence of umbilical hernias. Auscultation of the chest for clear symmetric breath sounds and abdomen for normal bowel sounds can be performed while the child is held by a parent, or after placing the child on the examination table. In small children, the sigmoid colon can often be palpated when it contains a large amount of fecal material.

Detection of an abdominal mass may be the first manifestation of a pathologic or non-pathologic process, such as a distended bladder, a multicystic dysplastic kidney, a hydronephrotic kidney, or Wilms' tumor.[11] Palpation of the abdomen should be initially soft, gentle, and superficial, and progress to a more deliberate, deeper palpation. The inguinal and scrotal areas can be assessed simultaneously, looking for asymmetry, hernias, hydroceles, and undescended testes.

Hydroceles should be closely examined to ensure that the testes can be palpated. Transillumination is frequently performed to demonstrate a fluid-filled hydrocele sac (Figure 1.1). Failure to identify a testis in a patient with a tense hydrocele should prompt further evaluation with a scrotal ultrasound if surgical exploration is not planned. Placing a hand over the inguinal area at the pubic tubercle before touching the scrotum will often prevent a retractile testis from ascending into the inguinal area (Figures 1.2 and 1.3). The position of the testes in the scrotum should be observed prior to touching the patient.

The examination of the scrotal contents should be performed during each visit despite the findings of scrotal testes on an earlier visit, to exclude the possibility of testicular ascent.[12] When a testis is undescended, sliding the examining hand lubricated with soap over the inguinal area will often demonstrate the location of the testis. The consistency and approximate size of the testes should be noted, as well as the stage of sexual development. As the boy reaches adolescence, the first sign of puberty is the growth of the testes, which usually occurs around 11–12 years of age, corresponding to a Tanner stage 2.[13,14] Secondary sexual development follows over the ensuing 1.5–3 years.

Figure 1.1 Transillumination of a hydrocele.

Figure 1.2 Physical examination of the groin and testis.

In girls, the first sign of puberty is usually breast development, followed by the appearance of pubic hair (Tanner stage 2). The onset of menses corresponds to a Tanner stage 4, and the corresponding external appearance for this stage of development is that of curly, coarse pubic hair, though less abundant than in adults, and the breast areola and papilla forming a secondary mound.[15]

Figure 1.3 Physical examination of the testis.

In the male patient, the examination of the penis is conducted next. The child to this point should be comfortable with the examination, and the transition to the examination of the penis should be painless and well tolerated by the patient. The presence of a foreskin and appearance of the glans should be noted, as well as the presence of any penile abnormalities including hypospadias, penile torsion, and chordee. Occasionally, the urethral meatus may be in an ectopic location in boys with hypospadias (Figures 1.4 and 1.5). In circumcised boys, the glans should be assessed for the presence of mucosal adhesions (Figure 1.6) or skin bridging (Figure 1.7). A hidden penis should be differentiated from the rare but more serious micropenis (Figure 1.8). When a micropenis is suspected, measurement of the stretched penile length with a ruler is necessary, while pressing the prepubic fat away. If the child remains cooperative, the various abnormalities identified during the examination should be demonstrated to the parents as part of their education into the child's urologic condition. In the normally uncircumcised male, the foreskin should be retractile in 90% by 5 years of age, though some residual glanular preputial adhesions may remain. Gentle, atraumatic retraction of the prepuce should be attempted. The location and size of the meatus should be noted, remembering that a small meatus on examination is not always indicative of urethral meatal stenosis (Figure 1.9). The appearance of the deflected urinary stream during the assessment of the urinary flow in the toilet-trained patient will determine if urethral meatal stenosis is present.[16] After examining the penis, the child is asked to turn to his side, or helped to do the same, to assess the anus, which can be inspected while pulling the but-

tocks apart. Anal winking often occurs during this maneuver. With the exception of cases of congenital anorectal malformations such as imperforate or anteriorly placed anus, abnormalities of the anus are rare in this age group.[2] Inspection should reveal a sym-

Figure 1.9 Meatal stenosis.

metrical pigmented perianal skin. A digital rectal examination should be reserved for special circumstances, such as a patient with urinary retention, assessment of the neurologically impaired child, or in cases of severe constipation, and it is best performed using a well-lubricated, gloved, small fifth finger. Examination of the lower backs and extremities completes the examination in the male child.

Examination of the genitalia in the preadolescent female is best conducted in the supine position with the legs in a frog-like position, with the soles of the feet touching each other. If this is not satisfactory, then a knee–chest position, asking the patient to perform Valsalva's maneuver, will allow satisfactory inspection of the introitus.[17] This should be the last part of the examination, and the girl may remain clothed until then. Practicing this part of the examination with a nurse prior to the physician conducting the genital examination may reduce the girl's apprehension related to the examination. To this effect, we often will tell the patient that a nurse is coming to help her undress, and to teach her a task. Talking to the girl and explaining what we are doing in a friendly, but professional, manner, is also helpful in comforting the patient. Depending on the age of the patient, the examination can be conducted while the girl remains in her mother's lap. If the child is placed on the examination table, the mother is encouraged to bend over to embrace the child and offer additional comfort. We ask the girl to try to touch the wall against the table with her knee, effectively encouraging her to flex and abduct her hips. After observing the external genital appearance, the labia majora are firmly, but not tightly, grasped between thumb and index finger, and pulled outwards and upwards, allowing full assessment of the open introitus, distal vaginal canal, and urethral meatus[18] (Figure 1.10). Any discharge or pooling of urine in the introitus should be further assessed with appropriate imaging studies. A pelvic examination, if necessary in the prepubertal female, should probably be conducted under general anesthesia, as manipulation and insertion of fingers or devices may have long-lasting psychologic consequences. Upon completion of the examination of the introitus, the girl is placed on her side to assess the appearance of the anus, as well as the cutaneous and bony aspects of the lower back. Attention should be given to the presence of dimples, scoliosis, discolored skin patches, or hairy nevi in this area. The examination of the lower extremities completes the examination, and particular attention should be given to symmetry, strength, and skin temperature.

When the child is uncooperative, the physician may rely on distraction techniques such as allowing him/her to play with a penlight, or toys, or hold an otoscope, to console the child. It is noteworthy that many patients who are uncooperative probably have had a negative experience with a healthcare provider in the past. If the child remains uncooperative, we should try to make the best of the situation, but never force an examination on the combative child. If an acute surgical condition is suspected, and the child is uncooperative, persevering with the examination with the use of assistants to gently restrain the combative child may be necessary. A useful technique to examine the abdomen and genitalia of anxious young boys is to have the mother embrace, and hold, the upper torso of the child against the examination table, while an assistant places the palms of their hands on the patient's thighs, close to the pelvis, to keep the body in place against the examination table. This allows the

Figure 1.10 Examination of the female introitus in an infant.

examining physician to conduct a quick and effective examination while the child is reassured by the closeness to the mother.

In pre- and postpubertal males, the physical examination should always include examination of the scrotal contents while the patient is standing, specifically to determine if a varicocele is present.[19] Failure to include this step in the physical examination will result in missing this common condition.

Finally, an uncomplicated neurologic examination can be easily performed in most children, and, in the context of the urologic patient, this part of the examination is usually reserved for patients with voiding disorders. Normal-appearing patients with genital disorders will rarely have neurologic conditions that can be uncovered by the urologist, and neurologic examination of the infant and young child by the urologist is usually unnecessary. In the older child and adolescent, the neurologic exam includes assessment of mental status, muscle tone, deep tendon reflexes, cerebellar function, and sensory responses.[2]

Key points

History in pediatrics

- Identify caretaker
- Privacy and confidentiality issues
- Establish relationship with the child and the parent
- Present illness and past medical history:
  - Urologic symptoms
  - Prenatal and neonatal history

Laboratory assessment of the pediatric urologic patient

2

Paul F Austin and Erica J Traxel

In general, laboratory assessment of the pediatric urologic patient is not as extensive as in the adult counterpart. Patients tend to be healthier and there are no recommended routine preoperative laboratory screening tests for pediatric urologic patients. However, there are certain instances when laboratory examination in pediatric urology is invaluable. This chapter will outline the most common laboratory tests used in pediatric urology, demonstrating the clinical scenarios in which each test should be employed.

Commonly ordered laboratory examinations

Urinalysis and urine culture and sensitivity

The most commonly utilized laboratory examinations in pediatric urology are urinalysis and urine culture and sensitivity. These urine tests are routinely ordered to identify a potential infection prior to invasive urologic procedures. A urinalysis with urine culture is also standard of care in investigating a fever of unknown origin in the infant. The prevalence of urinary tract infection (UTI) in pediatric patients with fever of unknown origin is 5%.[1] If a UTI is identified, the child requires more extensive testing to rule out further urologic pathology or anatomic abnormalities.

When children present with symptoms suggestive of a UTI such as dysuria, genital pain, diurnal enuresis, urgency, frequency, and urinary retention, it is important to understand that they may not have a UTI. These children may have a history of incomplete bladder emptying or a history of bladder and bowel holding termed 'dysfunctional elimination'.[2] A urinalysis and urine culture can help to discriminate between UTIs and the irritative voiding symptoms inherent to this group. Dysfunctional eliminators may have irritative voiding symptoms secondary to their behavior but they also have a higher risk of UTIs. When a UTI is identified, antibiotic treatment is essential acutely, but behavioral modification is the mainstay of treatment for children with dysfunctional elimination.[3]

It should be noted that there are certain instances in which the urinalysis should be interpreted with caution. In patients who perform clean intermittent catheterization, or who have undergone bladder reconstruction using intestinal segments, testing should be selective as a positive urinalysis in these patients may only represent colonization with bacteria. Antimicrobials are used when symptoms of infection, such as dysuria, pelvic pressure, and fever, accompany a positive urinalysis and urine culture. Overtreatment, however, may lead to the development of highly resistant organisms.[4–6]

Additionally, the method of collection can impact interpretation of laboratory urine tests. For example, a pediatric 'clean catch' urine specimen may yield growth not necessarily representative of an infectious process. In our practice we are careful to interpret urine collected from bagged specimens. Although a bagged specimen is a useful, non-invasive method for collecting urine from a non-toilet-trained child, this method can easily have a false-positive growth secondary to contamination from bacteria colonized on the genital and perineal skin. It is helpful when the bagged specimen results are negative or if there is a single isolate on the culture. It is also important to obtain both urinalysis and culture, as the absence of leukocytes in a specimen with positive culture should make one suspect contamination. If it is unclear whether there is truly infection, the urine specimen may need recollection via catheterization.

Serum blood urea nitrogen and creatinine

Serum blood urea nitrogen (BUN) and creatinine are frequently obtained as measures of renal function. When interpreting these tests, the clinician must be aware of the impact of the size of the child as well as their age. For example, the neonate's renal function is a reflection of maternal renal function at birth and the creatinine levels remains similar to the maternal serum creatinine for the first several days of life prior to decreasing to normal infant levels. Premature neonates in particular will have higher levels of creatinine and take longer to approach infant levels than full-term neonates.

Serum BUN and creatinine yield insight into renal function both as a baseline marker and as a method of longitudinal monitoring. With the diagnosis of prenatal and perinatal abnormalities, such as oligohydramnios (potentially secondary to bilateral renal agenesis, bilateral ureteropelvic junction (UPJ) obstruction, bilateral multicystic dysplastic kidney, or posterior urethral valves) or hydronephrosis (due to UPJ obstruction, congenital megaureter, posterior urethral valves, or vesicoureteral reflux), serum BUN and creatinine are important parameters that help determine the overall prognosis as well as monitoring therapeutic effectiveness. For example, a serum creatinine of more than 1.0 mg/dl at 1 year of age in a child with a history of posterior urethral valves is associated with poor renal outcome.[7] Other high-risk patients that require close monitoring of serum creatinine include patients with renal scarring that can be associated with vesicoureteral reflux[8] or with a neurogenic bladder.[9]

Complete blood cell count and coagulation studies

A complete blood cell count (CBC) and coagulation studies are not routinely obtained prior to most pediatric urology interventions. This is primarily due to the outpatient nature of pediatric urology procedures that are associated with low morbidity. There are certain patient populations, however, for whom these hematologic laboratory tests are indicated. These include children with chronic anemia or coagulopathic tendencies.

Important preoperative hematologic tests consist of a CBC, prothrombin time (PT), international normalized ratio (INR), and partial thromboplastin time (PTT). A lower than average hematocrit can be seen in children with sickle cell anemia and does not necessarily require intervention. If a value represents a significant change from baseline or if the patient is symptomatic or unstable, then hematologic intervention is recommended. Patients with von Willebrand disease will have poorly functioning platelets and possibly deficient levels of von Willebrand factor (vWF) VIII, with ensuing bleeding tendencies. In these patients it is advisable to obtain serum levels of vWF VIII, vWF ristocetin cofactor activity (vWFRCo), bleeding time (BT), as well as a CBC, PT, and PTT. Oncology patients are often pancytopenic, and procedures should be coordinated with chemotherapy cycles and administration of colony-stimulating factors, in order to maximize preoperative blood counts and minimize the chances for bleeding and infection. Clinical practice guidelines for platelet transfusion in patients with cancer have recently been published by the American Society of Clinical Oncology[10] and are essentially the same for children as for adults. With respect to surgery, or invasive procedures, these guidelines state the following: in the absence of associated coagulation abnormalities, a platelet count of 40 000/μl to 50 000/μl is sufficient to perform major invasive procedures with safety. For minor procedures, a lower threshold of 10 000/μl to 20 000/μl can be used.[10,11] If platelet transfusions are administered before a procedure, it is critical that a post-transfusion platelet count be obtained to prove that the desired platelet count has been reached. Platelets should also be available on short notice in case intraoperative or postoperative bleeding occurs. In summary, hematologic values must be considered within the context of careful clinical evaluation of each individual patient as well as the morbidity of the surgical procedure. Good communication with the pediatric hematologist will help steer the appropriate laboratory testing.

Common pediatric urologic clinical scenarios and requisite laboratory tests

Hematuria

When a child presents with hematuria, a number of tests are potentially indicated. Depending upon the degree of hematuria, and whether it is gross or microscopic, there are many potential etiologies (Table 2.1). Most hematuria originates in the renal parenchyma and is termed nephrologic hematuria. It is incumbent on the urologist to distinguish nephrologic bleeding from that caused by surgically significant sources.

Table 2.1 Differential diagnosis of hematuria in the pediatric population

Glomerular origin
IgA nephropathy
Alport's syndrome
Benign familial hematuria
Membranoproliferative glomerulonephritis
Acute post-streptococcal glomerulonephritis
Rapidly progressive glomerulonephritis
Systemic lupus erythematosus
Membranous nephropathy
Henoch–Schönlein purpura
Goodpasture's disease
Focal segmental glomerulosclerosis
Interstitial and tubular origin
Acute interstitial nephritis
Acute pyelonephritis
Tuberculosis
Hematologic disorders:
sickle cell disease, von Willebrand disease, renal vein thrombosis, thrombocytopenia
Urinary tract origin
Infection:
bacterial or viral, such as adenovirus
Nephrolithiasis
Structural/congenital anomalies:
UPJ obstruction, hydronephrosis, vascular malformation, polycystic kidney disease
Trauma
Tumors:
renal cell carcinoma, Wilms' tumor, transitional cell carcinoma
Exercise
Medications:
aminoglycosides, amitriptyline, anticonvulsants, aspirin, Coumadin (warfarin), cyclophosphamide, diuretics, penicillin, Thorazine (chlorpromazine)

Hematuria is often first noticed on a urine dipstick performed at the primary care office. A microscopic analysis of the urine should follow a positive dipstick. A freshly voided urine specimen should be used for this purpose. An approximately 10–15 ml aliquot of urine is spun in a centrifuge at 1500 rpm for about 5 minutes. The supernatant is decanted, and the sediment is resuspended in the remaining liquid and placed on a glass slide with a cover slip. Careful examination of the urine sample is then conducted under high-power magnification. All noncellular and cellular elements seen should be noted and recorded. The presence of more than 5 red blood cells (RBCs) per high-powered field (hpf) is generally considered abnormal. The detection of RBC casts is indicative of a glomerulotubular source of hematuria (Figure 2.1). The absence of RBCs and RBC casts despite a positive dipstick test is suggestive of hemoglobinuria or myoglobinuria. This is important because a positive urine dipstick for RBCs may have a completely negative microscopic examination and thus represent a false-positive result. Microscopic abnormal-shaped RBCs or dysmorphic RBCs are more commonly associated with nephrologic causes of hematuria, and normal-shaped or eumorphic RBCs are more commonly associated with urologic causes. The presence of proteinuria with dysmorphic RBCs further strengthens a nephrologic origin of the hematuria.[12]

Another practical test for microscopic hematuria in the outpatient clinic is a 'spot' urine calcium/creatinine ratio.[13–15] A ratio of >0.21 on two or three separate urine samples indicates hypercalciuria, although ratios can be significantly higher in infants. Hypercalciuria does not necessarily result in nephrolithiasis but is a reported risk factor.[16] A recent report indicates that the vast majority of children with hypercalciuria have a benign course and resolve with observation; therefore the rationale for doing this test routinely is less clear.[17,18]

It is important to note that the laboratory tests ordered for the evaluation of hematuria must be based on the clinical history and the physical examination. The physician should avoid automatically requesting tests that may be unnecessary. A panel of serum tests are selectively performed if renal and bladder sonog-

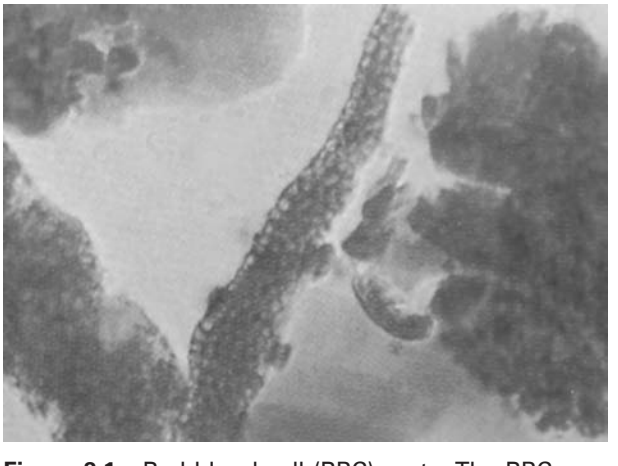

Figure 2.1 Red blood cell (RBC) casts. The RBCs are easily identified as biconcave disks embedded in the cast matrix. RBC casts are pathologic and their presence is usually indicative of severe injury to the glomerulus. Occasionally, RBC casts may be seen in an individual who has been playing contact sports. The urine will usually return to normal within 24–48 hours.

raphy are negative and the urine microscopy suggests a nephrologic origin. These tests, which include CBC, basic metabolic panel, serum complement levels, antistreptolysin O (ASO) titer, and antinuclear antibodies (Table 2.2), may subsequently indicate hematologic- or immunologic-mediated diseases affecting the kidney.

Testicular mass

A child presenting with a testicular mass should have testicular tumor markers obtained: these markers, including alpha-fetoprotein (AFP), human chorionic gonadotropin (HCG), lactate dehydrogenase (LDH), and placental alkaline phosphatase (PLAP), can be checked in the outpatient office setting or may be obtained in the operating room during the placement of the intravenous lines. These levels are important for staging as well as monitoring progress during treatment.

A serum AFP level will be elevated in tumors containing some component of yolk sac tumor, which is the most common nonseminomatous germ cell tumor in children. It will not be present in histologically pure choriocarcinoma or seminoma. Of note, serum AFP level at birth is relatively high and will remain so for the first several months of life, due to the yolk sac elements present during gestation (Table 2.3).[19] Additionally, AFP can be produced by the liver, pancreas, stomach, and lung; consequently, it may be elevated in diseases of these organs. In addition to ascertaining levels of tumor markers for testicular tumors, it is helpful to check liver function tests, as an elevation in these could indicate metastatic disease to the liver, which may or may not be visible on imaging.

Nephrolithiasis

The prevalence of nephrolithiasis in children is much smaller than in the adult population[20] and extensive laboratory assessment is recommended upon initial presentation. As opposed to the adult patient, nephrolithiasis in the pediatric population is more likely attributable to a metabolic abnormality. In the office, a urine dipstick can be performed to measure the urine specific gravity and pH. Microscopic examination of the spun urine can be performed to assess for RBCs and urinary crystals.[21,22] Calcium oxalate dihydrate crystals are seen as colorless squares with intersecting lines (resembling an envelope) (Figure 2.2). Calcium oxalate monohydrate crystals vary in size and may have a spindle, oval, or dumbbell shape. Most commonly, they appear as flat, elongated, hexagonal 'fence picket' crystals. Triple phosphate (struvite; magnesium ammonium phosphate) crystals usually appear as colorless, prism-like 'coffin lids' (Figure 2.3). Uric acid crystals may appear as yellow to brown rhombic plates, needles, or rosettes,

Table 2.3 Average normal serum alpha-fetoprotein levels of infants

Age	Mean ± SD (ng/ml)
Premature	134,734 ± 41,444
Newborn	48,406 ± 34,718
Newborn to 2 weeks	33,113 ± 32,503
Newborn to 1 month	9,452 ± 12,610
2 weeks to 1 month	2,654 ± 3,080
2 months	323 ± 278
3 months	88 ± 87
4 months	74 ± 56
5 months	46.5 ± 19
6 months	12.5 ± 9.8
7 months	9.7 ± 7.1
8 months	8.5 ± 5.5

Table 2.2 Serum panel for nephrologic hematuria

CBC
Basic metabolic panel
C3 complement level
Antistreptolysin O (ASO) titer
Antinuclear antibodies (ANA)

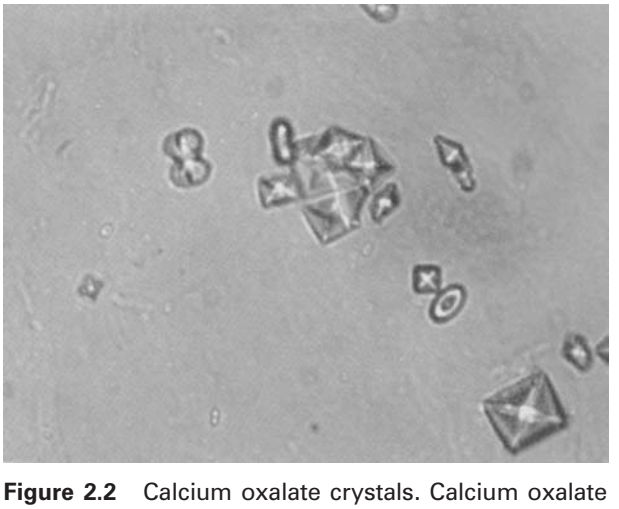

Figure 2.2 Calcium oxalate crystals. Calcium oxalate crystals most frequently have an 'envelope' shape and appear in acid, neutral, or slightly alkaline urine.

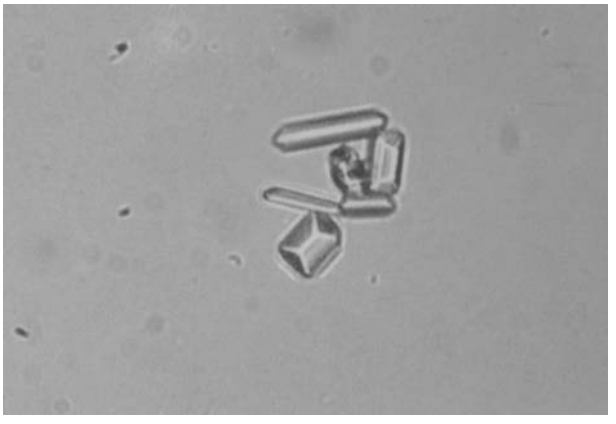

Figure 2.3 Triple phosphate crystals. These crystals are common in urine sediment. Triple phosphate crystals have a 'coffin-lid' shape, are colorless, and appear in alkaline urine. These crystals may be found with struvite or magnesium ammonium phosphate stones.

whereas cystine crystals have a characteristic hexagonal appearance (Figure 2.4).

Standard metabolic evaluation for pediatric nephrolithiasis includes serum tests and a 24-hour urine study (Table 2.4). A serum CBC, electrolytes, bicarbonate, calcium, phosphorus, BUN, creatinine, alkaline phosphatase, magnesium, and uric acid should be obtained. Elevated serum calcium suggests the possibility of hyperparathyroidism and a serum intact parathyroid hormone level should subsequently be checked. A 24-hour urine collection should be obtained on a regular diet, to check calcium, phosphorus, magnesium, oxalate, sodium, uric acid, citrate, cystine, creatinine, and volume.[23] The most common abnormalities seen on the 24-hour urine collection are

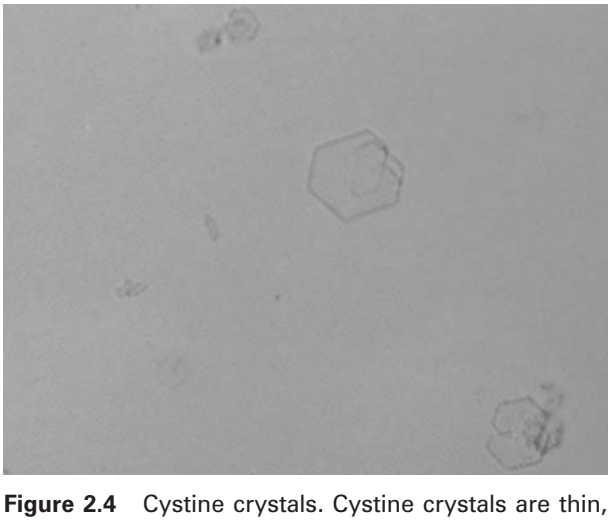

Figure 2.4 Cystine crystals. Cystine crystals are thin, hexagonal-shaped (6-sided) structures and appear in urine of children with cystinuria.

Table 2.4 Metabolic evaluation of pediatric nephrolithiasis

Serum	Urine – 24 hour
CBC	Volume
Basic metabolic panel	Calcium
Calcium	Oxalate
Uric acid	Citrate
Magnesium	Phosphorus
Phosphorus	Magnesium
Alkaline phosphatase	Sodium
	Uric acid
	Cysteine

diminished urinary volume indicative of poor hydration, hypocitraturia, and hypercalciuria.[24–27]

Intersex

The first laboratory tests ordered after a careful history and physical examination should be electrolyte assessment, a karyotype, and serum 17-hydroxyprogesterone (17-OH progesterone) levels. Obtaining electrolytes is important to identify any metabolic imbalances such as 'salt-wasting' seen in congenital adrenal hyperplasia (CAH) that would require prompt intervention. Serum 17-OH progesterone is obtained early because elevated levels identify CAH, which is the most common intersex condition. Formerly, the child's karyotype was obtained by a buccal smear but is now obtained by chromosome analysis of peripheral blood lymphocytes. A fluorescent in-situ hybridization (FISH) analysis may be done in conjunction with the chromosome analysis for rapid evaluation of sex chromosome presence. Although the FISH results will yield a karyotype within 24 hours, these results need verification from the formal chromosome analysis which takes 2–3 days. Further testing will then be directed accordingly (see Chapter 61).

Cryptorchidism

Nonpalpable testis in association with hypospadias requires an intersex work-up. Unilateral nonpalpable testis in the presence of normal external genitalia does not require additional laboratory investigation, although a newborn with bilateral nonpalpable testes and normal male genitalia must be evaluated for female pseudohermaphroditism due to CAH. Determination of the presence or absence of the unilateral undescended testicle is accomplished via surgical

exploration or diagnostic laparoscopy. In the case of bilateral, non-palpable undescended testes in an older child, further laboratory assessment can be done to ascertain the presence of testicular tissue.

A karyotype should be performed as well as measurement of serum testosterone in cases of bilateral, nonpalpable cryptorchidism. Additionally, the serum gonadotropins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), can be measured and if these are elevated in the face of low testosterone, this is suggestive of anorchia.[28] It is important to note that serum testosterone is normally elevated during infancy in the neonate, at 2–3 months of age as well as at puberty. Subsequently, serum testosterone can be measured in the neonate or during this natural surge of infancy. If this window of opportunity is missed or if evaluation is being done in the newborn period, then either a human chorionic gonadotropin (HCG) stimulation test may be obtained or a measurement of serum Müllerian inhibiting substance (MIS).

The level of serum MIS produced by the Sertoli cell is the most sensitive indicator of testicular presence,[29,30] but unfortunately the enzyme-linked immunosorbent assays (ELISAs) are not readily available in many centers. Subsequently, an HCG stimulation test is more frequently obtained. Several methods of HCG stimulation have been described.[31,32] One method is to administer HCG intramuscularly (100 IU/kg or 5000 IU/1.7 m^2) one time and measure serum testosterone and dihydrotestosterone 72 and 96 hours later.[31] Another method involves three intramuscular injections of HCG on successive days at a daily dose dependent on the child's age (≤1 year old, 500 units; 1–10 years old, 1000 units; ≥10 years old, 1500 units).[32] The HCG should stimulate testicular Leydig cells, if present, to produce testosterone, resulting in a level >200 ng/dl. If there is an appropriate increase in testosterone, then some functioning testicular tissue is present. If there is no response to HCG, then presumably the child is anorchid. However, there is also the possibility of Leydig cell dysfunction, in that the Leydig cells do not respond appropriately to HCG. For this reason, many pediatric urologists still perform exploratory surgery, regardless of laboratory results.

Nocturnal enuresis

Screening tests for nocturnal enuresis are necessary to rule out any organic etiology.[33] These tests include a urinalysis or urine dipstick to assess the urine specific gravity and the presence of glucose. If the specific gravity on the urinalysis is low, correlating to dilute urine, the possibility of diabetes insipidus (DI) is suggested. If the urinalysis or urine dipstick demonstrates large amounts of glucose, diabetes mellitus (DM) may be present. Subsequent work-up and testing can then be tailored accordingly.

Fetal urology and prenatal diagnosis 3

David F M Thomas

Introduction

The era of prenatal diagnosis dates from the late 1970s when case reports of the prenatal detection of urologic malformations first began to appear in the literature. Since that time prenatal diagnosis has rapidly become an established and routine feature of clinical pediatric urology throughout the developed world. Many aspects of prenatal diagnosis and the natural history of urinary tract malformations have been clarified by studies published in the last two decades, but some important questions relating to long-term outcomes remain unresolved. A detailed consideration of the investigation and practical management of the various anomalies detected by prenatal ultrasonography is detailed in the relevant chapters elsewhere in this book. This chapter will therefore focus predominantly on the following areas of fetal and perinatal urology:

- pathophysiology of urinary tract malformations
- current status of fetal intervention
- value of prenatal ultrasound in screening
- a rational approach to early postnatal investigation
- significance of mild dilatation ('pyelectasis')

Functional development of the normal urinary tract

Detailed embryology is beyond the scope of this chapter, and is covered elsewhere. A pivotal event in functional development occurs at around 32 days of gestation when the ureteric bud fuses with the metanephric mesenchyme to initiate the formation of excretory nephrons. Nephrogenesis proceeds by a process of reciprocal induction until the 36th week of pregnancy, with the glomeruli, proximal tubules, and loops of Henle being derived from the metanephros, whereas the collecting ducts, calyces, and renal pelvis are derivatives of the ureteric bud. In man, nephrogenesis ceases at 36 weeks, and thereafter the number of nephrons remains fixed at between 0.7 and 1 million per kidney. Major developmental defects dating from the first trimester of gestation are characterized by agenesis or dysplasia (arrested differentiation that is characterized histologically by immature tubules and the presence of aberrant mesenchymal derivatives such as smooth muscle and cartilage).

Urine production and excretory function

The primitive nephrons begin to excrete urine at around the 9th week of gestation. Initially, its composition resembles an ultrafiltrate of plasma, but as gestation progresses and tubular function matures, fetal urine begins to acquire the low electrolyte, high creatinine composition that characterizes normal urine in postnatal life.[1] Fetal urinary output at different stages in gestation has been documented by ultrasonography of the fetal bladder in healthy fetuses. By the third trimester, the hourly fetal urine production is as high as 30–40 ml/h and it constitutes around 90% of the amniotic fluid[2] (Figure 3.1). In the fetus the role of the kidney lies principally in fluid excretion, since homeostatic regulation of extracellular fluid composition is undertaken by the placenta. For this reason, creatinine clearance does not provide a meaningful measure of fetal renal function. However, extrapolation of values derived from iothalamate studies in the fetal lamb suggest that the fetal glomerular filtration rate (GFR) at 36 weeks of gestation approximates to only 5% of the surface corrected adult value.[3]

The kidney lung loop

Amniotic fluid, of which fetal urine is the major constituent, has long been recognized as playing a critical

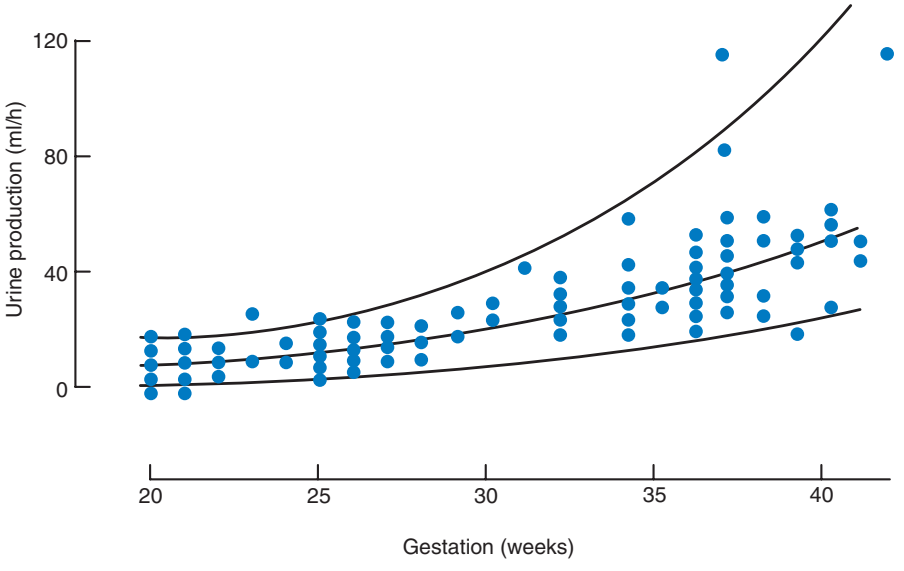

Figure 3.1 Fetal urine production at difference stages in normal pregnancy. (Adapted from Rabinowitz et al.[2])

role in lung development, and reduced amniotic fluid volume (oligohydramnios) is associated with varying degrees of pulmonary hypoplasia depending upon the timing and severity of the reduction in fetal urinary output. The role of amniotic fluid in promoting lung development probably extends beyond simple mechanical stenting of the airways, and renal-derived growth factors and other active agents are thought to be implicated in the regulation of early lung development.[4]

Changes at the time of birth

In the later stages of pregnancy, the fetus maintains a physiologic state of volume expansion. A high fluid intake of swallowed amniotic fluid is matched by a high obligatory urine output. If a comparable diuresis was maintained after birth, dehydration and volume depletion would rapidly supervene, but at the time of delivery, renal physiology rapidly switches to a fluid-restrictive mode, prompted in part by high circulating levels of aldosterone, vasopressin, and catecholamines. In addition, parenchymal perfusion and GFR increase dramatically in response to a fall in peripheral renovascular resistance and greatly increased renal perfusion. But, despite these adaptive changes, renal function remains marginal, with a corrected GFR at birth averaging only 30 ml/1.73 m^2. It is not until after 2 years of age that the GFR reaches the normal surface corrected adult value of approximately 125 ml/1.73 m^2.[5]

Pathophysiology of fetal uropathy

Defective nephrogenesis

Experimental ablation of the mesonephric duct (the origin of the ureteric bud) results in ipsilateral renal agenesis.

Renal dysplasia can be caused by a number of different mechanisms, including defective interaction between the ureteric bud and metanephric mesenchyme, intrinsic defects of differentiation, and a variety of extrinsic insults, notably obstruction. The classic observational studies of Mackie and Stephens[6] demonstrated the association between ureteral ectopia, faulty induction of nephrogenesis, and renal dysplasia in duplex systems. This 'ureteric bud hypothesis' can also be invoked to explain the association between renal dysplasia and high-grade reflux associated with ureteric ectopia.

More recently, studies using targeted gene ablation in 'knockout' mice have successfully reproduced a range of congenital abnormalities of the kidney and urinary tracts (CAKUT). Targeted mutations of the *AGTR2*,[7] *PAX2*,[8] and *UP3*[9] genes have been shown to give rise to congenital anomalies, including vesicoureteral reflux (VUR), with varying degrees of penetrance in experimental rodents. But while mutations of these and other genes have sometimes been implicated in the causation of urinary tract anomalies forming part of specific syndromes,[10] screening studies in children with isolated, non-syndromic urologic abnormalities have been almost entirely unrewarding.[11]

Fetal urinary tract obstruction

Upper tract

Experimentally, even brief periods of obstruction during nephrogenesis have been shown to induce apoptosis, aberrations of cell proliferation, and transdifferentiation of mesenchyme into the phenotypes that characterize renal dysplasia. Gene expression is also disrupted by obstruction.[12] However, the results of experimentally created obstruction in animal models must be interpreted with some caution in view of the difficulty in reproducing a model of chronic, partial upper tract obstruction – the pattern most commonly encountered in clinical practice.

Lower tract: bladder outlet obstruction

Experimentally induced infravesical obstruction was extensively studied by Harrison and his colleagues in San Francisco in the 1980s.[13] For example, these authors induced partial urethral obstruction in fetal lambs at 93–107 days of gestation. They then showed that the hydronephrosis, urinary ascites, and fatal pulmonary hypoplasia which ensued in untreated fetal lambs was reversed when the obstructed bladder was subsequently decompressed in utero. These and other studies underpinned the scientific rationale for introducing intrauterine bladder drainage in clinical practice. Unfortunately, subsequent experience with fetal intervention in the clinical setting suggests that some of the findings in the fetal lamb model may not translate to man. The current status of fetal intervention is considered in more detail below.

Fetal vesicoureteral reflux

The pattern of severe damage associated with grade V reflux can reasonably be ascribed to dysplasia resulting from a ureteric bud defect. By contrast, kidneys exposed to mild or moderate reflux in utero often appear normal or show global reduction in size with smooth outline (hypoplasia) on technetium 99m (^{99m}Tc) dimercaptosuccinic acid (DMSA) imaging. Focal scarring is predominantly a feature of postnatal infection.[14]

Very little is known of the mechanisms of renal damage seen in conjunction with sterile fetal reflux but in one fetal lamb model, experimentally induced VUR has been shown to exert significant changes on tubular function and on postnatal DMSA appearances of the kidneys.[15] In addition, clinical evidence is accumulating to indicate that even in the absence of infection high-grade bilateral primary reflux in males carries a greater risk of renal impairment than was previously recognized.[16] While the 'water hammer' effect of sterile urine has been largely discounted as a cause of ongoing postnatal renal damage, this mechanism may exert a more significant impact in the fetus.

Fetal intervention

In contrast to the evidence-based approach developed by Harrison's group in San Francisco, obstetricians in many other centers enthusiastically adopted fetal intervention on an uncritical and unreported basis in the 1980s. Where results were published, they were uniformly disappointing. The Fetal Surgery Register[17] reported an overall mortality rate of 59% in 73 fetuses – but this was probably an overoptimistic assessment, since an accurate urologic diagnosis was not established in many cases. By the end of the 1980s, enthusiasm for fetal intervention was waning. Mandell et al[18] identified 24 related publications between 1982 and 1985, but only 7 publications between 1985 and 1989, of which two were single-case reports. Although bladder decompression was initially achieved by open fetal surgery, this was soon abandoned in favor of vesicoamniotic shunting using an ultrasound-guided suprapubic pigtail catheter[19] (Figure 3.2). This remains the favored approach,

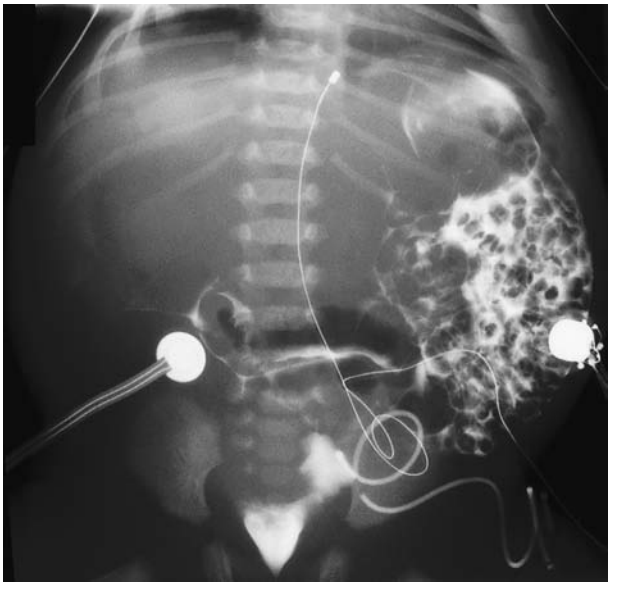

Figure 3.2 Complication of vesicoamniotic shunting. A postnatal contrast study reveals intraperitoneal placement of shunt with extravasation of contrast and urinary ascites. Despite shunting, this neonate succumbed to pulmonary hypoplasia.

although fetoscopy and intrauterine valve ablation have also been described.[20] Medium- to long-term outcome results have been reported by some centers which continue to undertake fetal intervention on a responsible and audited basis. In Detroit, Freedman and associates[21] documented the outcome of vesicoamniotic shunting in 34 fetuses treated during the period 1987–1996. Of these, only 17 survived to term, of whom 14 were assessed after 2 years minimum follow-up. Eight of these 14 children had already progressed into end-stage renal failure and 5 had been transplanted at the time of the study. Thus, of the original total of 34 shunted fetuses, only 6 were alive with normal renal function when assessed after 2 years of age. In another long-term study, the San Francisco group[22] analyzed the late outcome of 36 fetuses treated in the period 1981–1999. All had been selected for treatment on the basis of favorable urinary biochemistry. Of the 36 treated fetuses, 14 had a diagnosis of posterior urethral valves – of whom 6 did not survive to term. However, 8 infants with prenatally detected urethral valves treated in utero did survive and were evaluated at the mean of 11.6 years – when 5 were in renal failure. In all, only 3 (21%) of the 14 fetuses with posterior urethral valves survived with normal renal function. From a meta-analysis of published series totaling 342 fetuses, Clark et al[23] concluded that 'amongst controlled studies bladder drainage appeared to improve perinatal survival relative to no drainage.' Nevertheless, these authors cautioned that this positive conclusion might be influenced by a subgroup of fetuses with poor prognosis who had experienced a particular benefit in terms of early survival.

In summary, if survival is taken as the endpoint, there is reasonable evidence that intrauterine intervention ('fetal surgery') is effective, probably by facilitating lung development. Unfortunately, this does not appear to be true of renal development, since a high proportion of infants who have been treated in utero nevertheless progress rapidly into end-stage renal failure – with significant implications for their quality of survival in childhood and later life.

Prognostic indicators: selection for fetal intervention

Ultrasound

Bladder dilatation, regardless of the underlying cause, tends to carry a poor prognosis when detected before 24 weeks of gestation. A study in the author's unit demonstrated a marked difference in outcome between boys with prenatally detected posterior urethral valves identified before 24 weeks of gestation when compared with boys whose second trimester scans were normal and dilatation only became apparent on scans in later pregnancy. In the first group, 24% of boys died of pulmonary or renal failure following delivery and a further 29% progressed into early-onset renal failure. By contrast, when the second trimester scan was normal, none of the boys with posterior urethral valves succumbed in infancy and 93% had normal renal function at the time of follow-up.[24]

A high risk of poor prognosis and early-onset renal failure can be predicted from the following features:

1. Detection of dilatation before 24 weeks of gestation.
2. Male fetus.
3. Distended and/or thick-walled bladder.
4. Moderate or severe upper tract dilatation: corresponding to renal pelvic anteroposterior (AP) diameter of >10 mm before 24 weeks of gestation.
5. Abnormal renal parenchyma: microcystic or 'bright' parenchyma on ultrasound.
6. Oligohydramnios.

Biochemical markers

Since measures of renal function such as creatinine clearance are invalid in the fetus, the assessment of fetal renal function has relied mainly on analysis of biochemical markers in the fetal urine.

Urinary constituents that have been identified as predictors of poor functional outcome include a urinary sodium of >100 mEq/L after 20 weeks of gestation, elevated urinary calcium (>1.2 mmol/L), and elevated levels of urinary β_2 microglobulin.[25] Although serial sampling improves prognostic sensitivity, specificity is often poor, with considerable scatter and overlap of normal and abnormal values. Nicolini and Spelzini[26] have documented instances of fetuses with significant renal dysplasia where the initial urinary parameters were normal but then deteriorated progressively throughout the pregnancy. In the hope of improving sensitivity, attention has switched from markers of excretory renal function to molecules which are expressed during renal differentiation and which are regulated in renal dysplasia, such as transforming growth factor-β_1 (TGF-β_1).[27]

Summary: current status of fetal intervention

Long-term outcome studies and a growing body of anecdotal evidence indicate that fetal intervention

does have the potential to increase survival by reducing the risk of pulmonary hyperplasia. By contrast, there is very little evidence that the prognosis for renal function is significantly improved by fetal intervention – probably because this is largely determined by dysplasia which predates diagnosis and treatment.

Indeed, it seems highly likely that some infants who might otherwise have succumbed to pulmonary hypoplasia have survived as a result of fetal intervention only to progress rapidly into end-stage renal failure in infancy or early childhood. Ransley[28] has consistently argued that our perception of fetal intervention has been colored by poor outcomes in bad prognosis cases and has suggested that the potential benefits of fetal intervention might be more apparent if it was extended to include all male fetuses with evidence of outflow obstruction in the second trimester. Unfortunately, it would require a prospective controlled study extending over many years to put Ransley's hypothesis to the test, since the full extent of renal insufficiency associated with congenital outflow obstruction is often not apparent until late childhood or adolescence. In addition, one might anticipate that parents who have been fully counseled on the implications of renal failure (dialysis, repeated hospitalization, transplantation including the likely requirement for a second transplant), would opt either for fetal intervention or termination of pregnancy rather than participate in the control arm of any study.

Screening for urologic anomalies

In countries with comprehensive healthcare systems the overwhelming majority of women are scanned by ultrasound at least once in pregnancy. Screening occurs at two levels: first, as part of formal screening for major fetal anomalies; and secondly, as an informal, ad-hoc screening process in which urinary tract anomalies are detected incidentally during the course of the third trimester scanning – usually for obstetric indications.

Nuchal pad transluscency is being used increasingly for screening at 10–12 weeks of gestation in high-risk pregnancies, particularly for Down syndrome. Although some structural abnormalities can be detected at this stage in gestation, the urinary tract is barely functional and the sensitivity of ultrasound for the detection of urinary tract anomalies in the general fetal population is unacceptably low.

Fetal anomaly screening

By contrast, the diagnositic sensitivity of ultrasonography is greatly increased by 17–20 weeks, the time when fetal anomaly scanning is routinely undertaken in the United Kingdom. In a 3½ year prospective study in the Yorkshire region, 2261 anomalies were identified on ultrasound, of which 369 (16%) prompted termination of pregnancy.[29] Autopsy and cytogenetic evaluation was performed in 97% of aborted fetuses. Central nervous system malformation accounted for almost 50% of terminations, whereas the genitourinary tract was the second most commonly affected system, accounting for 35 (9.5%) of the 369 terminations. Bilateral renal agenesis and multicystic renal dysplasia (Figure 3.3) were the most common lethal anomalies, followed by urethral obstruction and polycystic kidneys. No false-positive results were encountered, confirming a high level of

Figure 3.3 Bilateral multicystic renal dysplasia: autopsy findings following termination of pregnancy.

specificity for second trimester fetal anomaly screening for the detection of major urinary tract malformations.

Scott[30] analyzed 560 deaths in 2857 fetuses, neonates, and infants with urinary tract anomalies during a 6-year period in the Northern Region Congenital Abnormality Survey in the UK.

Of these 560 deaths, 68% occurred in utero (termination of pregnancy, intrauterine death, and stillbirth), whereas 32% occurred postnatally, most commonly from pulmonary hypoplasia.

Termination of pregnancy

Attitudes to termination of pregnancy ('therapeutic abortion') for severe congenital anomalies vary considerably between different countries. In most western European countries, including those that espouse Roman Catholicism, termination of pregnancy for fetal anomalies is legal (subject to gestational age and obstetric criteria), and is widely practiced. The situation is somewhat different in the United States where access to antenatal care (including second trimester ultrasonography), is more limited in certain socioeconomic groups and where abortion is a more divisive political issue.

Termination of pregnancy is already exerting a striking impact on pediatric urologic practice. Cromie et al[31] documented the outcome of 163 431 pregnancies recorded on the malformation surveillance program in Boston between 1974 and 1994. These authors found that elective termination of pregnancy had been undertaken in 65% of pregnancies following detection of myelomeningocele, 46% of pregnancies following prenatal diagnosis of posterior urethral valves, 31% for prune belly syndrome and 25% for bladder exstrophy. In the UK, termination of pregnancy is almost certainly being undertaken on a comparable or greater scale. The numbers of newborn infants being born with open spina bifida has declined dramatically over the last two decades and it is increasingly rare to encounter new cases of prune-belly syndrome (Figure 3.4). Similarly, the numbers of newborns with severe but nonlethal and potentially reconstructable anomalies such as 'classical' bladder exstrophy or cloacal exstrophy (Figure 3.5) are rapidly declining. As a consequence of the diminishing bladder exstrophy workload only two referral centers in England and Wales are now authorized to treat new cases.

Males with obstructive uropathy (predominantly posterior urethral valves) account for up to 90% of children aged 0–4 years old requiring renal replacement therapy (dialysis and/or transplantation).[32] These individuals can now be identified with considerable accuracy in the second trimester, and if parents were to opt increasingly for termination of pregnancy this would be reflected in declining numbers of children on end-stage renal failure programs in the first 5 years of life. In turn, this would have implications for pediatric nephrology workload.

Figure 3.4 Newborn infant with characteristic features of prune belly syndrome, which is a disappearing disorder. Most major centers report a dramatic decline in incidence following the advent of prenatal diagnosis and termination of pregnancy.

Screening for nonlethal uropathies

The increasing use of ultrasound for a variety of obstetric indications in the third trimester constitutes a further, informal means of detecting urologic abnormalities.

But whereas ultrasonography detects severe, potentially lethal anomalies with a high degree of sensitivity it is far less reliable for detecting anomalies of mild to moderate severity. The diagnostic sensitivity

Figure 3.5 Cloacal exstrophy. Although cloacal and uncomplicated forms of bladder exstrophy are not generally associated with a significant risk of renal failure, prenatal diagnosis and possible termination of pregnancy raise serious ethical issues relating to quality of life.

of the ultrasound finding of isolated upper tract dilatation ('fetal hydronephrosis') is low, since these appearances may denote active obstruction, non-obstructive dilatation, a simple anatomic abnormality ('extrarenal pelvis'), or VUR. Ureteral dilatation may be due to reflux, obstructive or non-obstructive megaureter, or upper tract changes due to bladder dysfunction or infravesical obstruction. In the majority of instances, therefore, it is impossible to establish a definitive urologic diagnosis without the additional information provided by appropriate postnatal imaging. However, unilateral multicystic dysplastic kidney and duplex kidney are examples of anomalies which can be diagnosed with reasonable certainty – although confirmatory postnatal imaging is still required.

Defining 'pathologic' dilatation

Many studies have tried to establish a predictive 'cut-off' value for the AP diameter of the renal pelvis which is indicative of clinically significant pathology. Although 1 cm has been widely used, Livera et al[33] found that fewer than 50% of infants with this degree of dilatation detected at 28 weeks subsequently proved to have significant pathology.

Scott and Renwick[34] undertook a comprehensive analysis of 1301 fetal renal pelvic measurements at different gestational ages and correlated the values with postnatal outcomes. These authors concluded that 'a measurement of the fetal renal pelvis of 7 mm or greater at gestational age of 18 weeks is a strong indication that the urinary tract may be abnormal and should be carefully observed during the later stages of pregnancy.' In the author's unit, a study of 35 children with prenatally detected ureteropelvic junction (UPJ) obstruction demonstrated a broad correlation between the AP diameter of the renal pelvis in the second trimester and the severity of functional impairment on postnatal renography.[35] However, this only reached statistical significance in a small group of kidneys with an AP diameter >15 mm in the second trimester (in which postnatal mean differential function was reduced to 26.5%), whereas in the AP diameter range 6–15 mm (the range most commonly encountered in clinical practice) the predictive value was less consistent, with considerable scatter of values for postnatal function.

Dhillon et al[36] found that when the AP diameter was ≤15 mm, this measurement had a strong negative predictive value, since the risk of functional deterioration due to UPJ obstruction was only 2% (Table 3.1).

To summarize, severe dilatation confined to the renal collecting system, particularly when detected in the second trimester, is a reasonably sensitive predictor of significant obstruction. However, by the later stages of pregnancy the risk of obstruction causing functional impairment is largely confined to those kidneys with an AP diameter >15 mm.

Postnatal evaluation: general considerations

The most immediate threat faced by a newborn infant with a urologic abnormality is urinary infection – particularly when this is associated with outflow obstruction or high-grade reflux. Initial investigation should therefore be aimed at identifying infants at greatest risk, principally boys with posterior urethral valves or high-grade primary reflux. On the other hand, the importance of identifying the relatively small proportion of infants with serious pathology must be balanced by the need to avoid submitting large numbers of healthy asymptomatic infants to needless and often invasive investigations. A selective approach is

Table 3.1 Prenatally detected ureteropelvic junction obstruction: correlation between maximum recorded anteroposterior (AP) diameter of renal pelvis and likelihood of impaired differential function on initial postnatal evaluation or during follow-up

Maximal AP diameter of renal pelvis (mm)	Requirement for surgical intervention (based on functional criteria) (%)
<15	2
15–20	7
20–30	29
30–40	61
40–50	67
>50	100

Findings derived from prospective studies undertaken at the Hospital for Sick Children, Great Ormond Street, London.[36]

required, guided initially by the pre- and postnatal ultrasound findings.

Ultrasonography

Since the urinary output of newborn infants is reduced in the first 24 hours of life, it is generally recommended that ultrasonography is deferred for 24–48 hours until a more physiologic urinary output has been re-established. Although this remains the ideal, the risk of missing significant pathology as opposed to mild dilatational reflux has probably been overstated. Moreover, with the trend to earlier hospital discharge following delivery, this optimal timing may not be feasible. In the author's view, the principal indications for an early (24–48 hours) scan prior to discharge are as follows:

1 *Distended and/or thick-walled bladder, bilateral upper tract dilatation, ureteral dilatation*. These prenatal ultrasound findings suggest lower urinary tract obstruction. Relevant clinical findings may also be present, such as a palpable bladder or poor urinary stream.
2 *Bilateral renal dilatation without bladder or ureteral dilatation*. These findings are of greater significance in males, in whom they may denote posterior urethral valves or high-grade primary reflux. Nevertheless, ultrasound imaging can reasonably be deferred until 3–7 days of age if it is not feasible to proceed to imaging in the first 48 hours of life.

Where prenatal ultrasonography has demonstrated isolated unilateral renal dilatation, a duplex kidney, or a unilateral multicystic dysplastic kidney with a normal contralateral kidney, the initial postnatal scan can reasonably be deferred for up to 10–14 days, although a scan between 3 and 7 days remains preferable.

Formal measurement of the anteroposterior diameter of the renal pelvis is now routinely performed in most specialist centers. Although influenced by the state of hydration and other factors, measurement of the AP diameter is still preferable to subjective descriptions such as 'mild' or 'moderate' dilatation, 'full' or 'baggy' renal pelvis, etc. The grading system developed by the Society for Fetal Urology (SFU)[37] encompasses the appearances of the collecting system, 'central renal complex' and renal parenchymal thickness (Table 3.2), and these aspects of the ultrasonographic appearances should still be documented even if the formal SFU protocol is not followed. Evidence of ureteral dilatation should be sought and the bladder should be assessed for features such increased wall thickness and postvoid residual.

Voiding cystourethrography

Although opinion remains divided on the precise role of voiding cystourethrography (VCU) in postnatal evaluation, there is a growing consensus in many specialist units that a VCU is no longer mandatory in infants with isolated unilateral renal pelvic dilatation. A more selective approach has the benefit of reducing the numbers of healthy children subjected to an unnecessary and invasive investigation. In the author's practice the indications for an early VCU are as follows:

1 Abnormal appearances of the bladder – particularly thick-walled bladder or other evidence of outflow obstruction (e.g. 'keyhole' configuration indicative of posterior urethral valves).

Table 3.2 Classification of prenatal hydronephrosis (Society for Fetal Urology)

Renal image		
Grade of hydronephrosis	Central renal complex (intrarenal pelvis, calices)	Renal parenchymal thickness
0	Intact	Normal
1	Slight splitting	Normal
2	Evident splitting, complex confined within renal border	Normal
3[a]	Wide splitting, pelvis dilated outside renal border, *and* calices *uniformly* dilated	Normal
4	Further dilatation of pelvis and calices (calices may appear convex)	Thin

Grade of ureteral dilatation (UD Gr)	
UD Gr	Diameter of ureter (mm)
1	<7
2	7–10
3	>10

[a]An extrarenal pelvis extending outside the renal border which is not accompanied by caliceal dilatation corresponds to grade 2 hydronephrosis.
The grading system was devised as a guide to postnatal assessment but can also be used in the third trimester to counsel parents on the clinical significance, or otherwise, of prenatal sonogram findings.
From Maizels et al.[37]

2 Ureteral dilatation visualized on either pre- or postnatal ultrasound.
3 Duplex kidneys – in view of the high incidence of lower pole reflux.
4 Bilateral upper tract dilatation in a male fetus or infant.

Voiding cystourethrography should always be undertaken under antibiotic cover using a catheter or feeding tube – which should be left in the bladder when urethral obstruction is demonstrated. If there is already strong presumptive evidence of posterior urethral valves, it may be advantageous to perform the VCU via a percutaneously inserted neonatal suprapubic catheter.

Antibiotic prophylaxis

There is very little evidence on which to base reliable guidelines. As a rule, however, antibiotic prophylaxis is a prudent precaution for all newborn infants with prenatally detected uropathies, pending the outcome of postnatal investigations (particularly VCU). However, antibiotic prophylaxis may not be required for the following, although it is still generally prescribed:

- isolated renal dilatation with an AP diameter of 10 mm or less
- unilateral multicystic dysplastic kidney with a normal contralateral kidney and no evidence of contralateral or ipsilateral ureteric dilatation
- an ectopic but otherwise normal kidney.

Isotope imaging

By contrast to infection, obstruction per se rarely poses an urgent threat and thus the information provided by functional imaging does not usually influence immediate management. ^{99m}Tc DMSA is best suited for confirming total absence of function in a multicystic dysplastic kidney or for documenting differential function and patterns of parenchymal damage associated with VUR. Dynamic renography with ^{99m}Tc mercaptoacetyltriglycine (MAG3) is used primarily for the diagnosis of obstruction. Whereas furosemide washout is an essential element of the study, the interpretation of drainage curves is often problematic in young infants during the period of 'transitional' renal function.

Since the information derived from diuretic renog-

raphy is rarely crucial in the first few weeks or months of life, this investigation can generally be deferred for 4–6 weeks, when the results can be interpreted more reliably.

Suggested protocols for postnatal imaging

Suggested protocols for postnatal imaging are illustrated in Figures 3.6–3.9. The investigative pathway is determined initially by pre- and postnatal ultrasound findings and it may occasionally be necessary to switch to a different plan of imaging if the original diagnosis is revised in the light of further information.

Commonly prenatally detected uropathies

A detailed consideration of the investigation and management of individual urinary tract malformations appears elsewhere in the relevant chapters of this book but some of the key points can be briefly summarized as follows.

Ureteropelvic junction obstruction

The management of prenatally detected UPJ obstruction has generated considerable controversy and the evolution of a more selective approach to surgery can be largely credited to Ransley's group[39] and Koff.[40] In addition to documenting the potential for the condition to resolve spontaneously, these and other authors have confirmed the relative safety of selective conservative management. Some of the more consistent themes to emerge from the literature are:

1. Significant loss of function which has occurred in utero does not usually recover despite relief of obstruction by pyeloplasty.
2. The probability of significant functional impairment at the time of birth or the subsequent risk of functional deterioration is linked to the severity of dilatation, with the risk of functional impairment being <10% where the AP diameter of the renal pelvis is <20 mm.
3. Conversely, an AP diameter of >35 mm denotes obstruction carrying a significant risk of functional impairment.
4. The risk of functional deterioration on conservative management is low, providing differential function in the obstructed kidney exceeds 40% and the maximum recorded AP diameter of the renal pelvis is <30 mm.

Posterior urethral valves

In many healthcare systems, between 50% and 80% of boys with this condition are now identified prenatally (Figures 3.10 and 3.11). Prenatal diagnosis has undoubtedly been a major factor in the dramatic reduction in early mortality since the 1980s, but the impact of prenatal diagnosis on the long-term burden of end-stage renal failure is less certain. It is becoming clear that even when prenatal diagnosis has resulted in prompt and optimal management, a sizeable proportion of individuals with this condition are nevertheless continuing to progress into end-stage renal failure in late childhood or adolescence. Whether the greater use of fetal intervention would reduce this burden of long-term morbidity remains an unanswered question.

Vesicoureteral reflux

Primary VUR accounts for 15–20% of prenatally detected uropathies. In addition, low-grade non-dilating VUR may be identified as an incidental finding on a VCU performed as part of the routine evaluation of a coexisting prenatally detected uropathy. Prenatally detected VUR is predominantly a disorder of male infant, with males outnumbering females by a ratio of up to 5 to 1.[41] Urodynamic studies in male infants with high-grade VUR have revealed marked bladder dysfunction,[42–44] which has been attributed by some authors to the legacy of transient urethral obstruction in utero – for example, by Cowper's duct cysts.

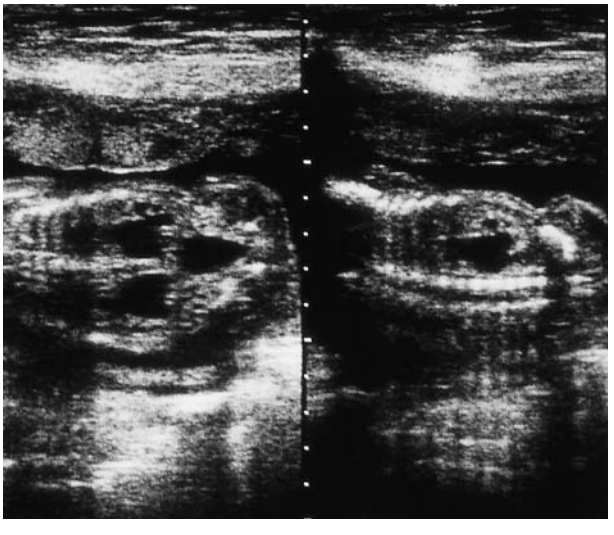

Figure 3.10 Posterior urethral valves: the fetal spine and thoracic cage are clearly visualized. Bilateral hydronephrosis and bladder distention can be seen.

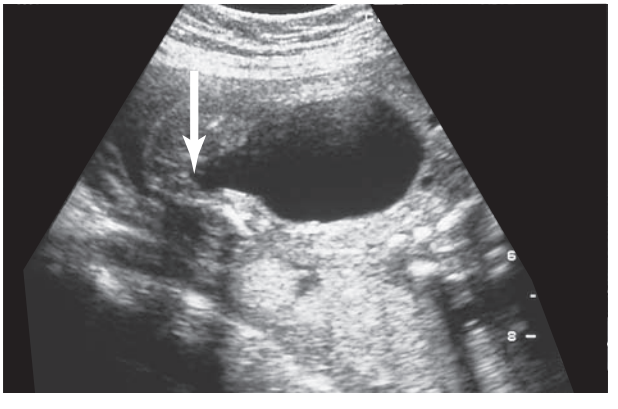

Figure 3.11 'Keyhole' sign. Dilatation of fetal bladder accompanied by distinctive dilatation of posterior urethra (arrow) and posterior urethral valves.

Regardless of any underlying cause, prenatally detected VUR seems to have a greater potential to resolve spontaneously than clinically presenting reflux. Reviewing the outcome of 413 prenatally detected refluxing units reported in 7 published series, Elder[45] noted an overall figure for spontaneous resolution of 78% for grades I–III VUR and 36% for grades IV and V. Conservative management was effective in the majority, with only 13% of children developing urinary infections during the course of follow-up.

Where breakthrough urinary infection necessitates surgical intervention in the early months of life, the author's preference is for cutaneous vesicostomy, but thereafter ureteral reimplantation is performed.

Multicystic dysplastic kidney

The introduction of prenatal ultrasonography revealed that the true prevalence of multicystic dys-

plastic kidney (MDK) is far higher than was previously recognized.[46,47] The natural history of prenatally detected MDKs is characterized by shrinkage or complete involution – which can also occur in utero, mimicking renal agenesis.[48]

Although there are reports of MDK occurring on a familial basis, it more commonly behaves as a sporadic anomaly. A study undertaken in the author's unit documented three affected families, one of whom demonstrated a pattern consistent with autosomal dominant inheritance with variable expressivity.[49] Ultrasound screening of 94 first-degree relatives of 29 children with prenatally detected MDK did not identify any significant renal anomaly. For this reason, we do not advocate formal screening on the families of children with MDK. The management of prenatally detected MDKs is considered elsewhere.

Mild dilatation (pelviectasis)

Mild collecting system dilatation, typically a renal pelvic diameter in the range 5–10 mm (Figure 3.12), is a feature of approximately 1 : 100 pregnancies. However, this is often a transient phenomenon. For example, Sairam[50] reported an 80% resolution rate for dilatation in the range 4–6 mm. Likewise, Chitty et al[51] followed 475 fetuses with mild dilatation detected between 16 and 26 weeks' gestation, and documented complete resolution or improvement in 66% on re-evaluation in the third trimester.

Pelviectasis is sometimes cited as a possible marker for aneuploidy. However, in a study of 25 586 unselected low-risk pregnancies, Havutcu et al[52] documented a 1.25% incidence of mild dilatation (mean AP diameter 6.4 mm, range 5–15 mm) but found no cases of aneuploidy. These authors concluded that the 'risk (of aneuploidy) in isolated fetal pyelectasis in low-risk populations is so small that it should not be an indication for invasive prenatal karyotyping.' Although the weight of reliable evidence indicates that isolated dilatation is not a marker of aneuploidy, when this finding occurs in conjunction with other anomalies it is more strongly indicative of an underlying genetically determined anomaly or syndrome.

Figure 3.12 Bilateral renal pelvic dilatation. Anteroposterior diameter = 1.0 cm at 26 weeks' gestation. No underlying pathology was identified on postnatal investigation.

Mild dilatation and vesicoureteral reflux

Although isolated mild dilatation (pelviectasis) can be largely discounted as an indicator of aneuploidy or significant upper tract obstructions, it can denote underlying VUR. In a prospective study of 5643 fetuses undertaken by Ismali et al,[53] mild dilatation or 'pyelectasis' (defined as AP diameter of >4 mm in the second trimester and an AP diameter in the range 7–15 mm in the third trimester) was found in 258 fetuses. Subsequent voiding cystourethrography in these individuals identified an overall incidence of VUR of 10.7%.

In a smaller study, Gloor et al[54] documented an incidence of VUR of 15% in 22 infants with dilatation in the range AP diameter 4–10 mm detected before 24 weeks' gestation. In practice, however, the morbidity generated by mild dilatation is minimal. In the author's unit, a follow-up study totaling 122 child-years of follow-up identified only two incidences of morbidity related to the urinary tract, neither of which were due to reflux.[55] DeJong et al[56] undertook a questionnaire case control study in children aged 4–9 years old to compare the incidence of urinary tract symptoms in children with a history of prenatally detected mild dilatation with normal controls. No difference was found in the incidence of either urinary tract infection or incontinence between the two groups.

Thus, there appears to be increasingly little justification for routinely submitting infants with prenatally detected isolated pelviectasis to voiding cystourethrography, an invasive and potentially distressing procedure which will yield negative results in 85–90% of cases. Some instances of predominantly low-grade, self-limiting VUR (mainly in boys) will be missed by this selective approach, but this risk is outweighed by the benefit of reducing the burden of unnecessary investigation in large numbers of healthy infants.

Nevertheless parents should be involved in the decision-making process, whenever possible, since there is a very small risk of VUR that might be destined to give rise to infection and scarring. If parents decide against a VCU, both they and their primary care physicians should be alerted to the need for the urine to be checked promptly for possible infection if the child develops an unexplained febrile illness or urinary symptoms.

Conclusion

Ultrasonography is now so firmly rooted in obstetric practice that it would be unthinkable for pediatric urology to return to the preultrasonography era. In general, prenatal diagnosis must be considered to have been beneficial, but it must also be acknowledged that the detection of mild dilatation and some asymptomatic anomalies has generated needless parental anxiety and unnecessary investigation. In many countries the impact of termination of pregnancy is already evident in a substantial decline in new cases of prune belly syndrome (see Figure 3.4), cloacal and 'classic' bladder exstrophy and neuropathic bladder associated with open meningomyelocele. As termination of pregnancy extends to include other severe, nonlethal fetal uropathies the number of infants and young children requiring renal replacement therapy and transplantation (predominantly males with urethral obstruction and renal dysplasia) may also diminish.

Prenatal ultrasonography has undoubtedly advanced our understanding of the functional development of the urinary tract and the pathophysiology of many urinary tract malformations. In the future, this will be complemented by important discoveries within the rapidly advancing science of developmental biology to provide pediatric urologists with a much greater understanding of the scientific foundations of the specialty.

Office ultrasonography

4

Dennis B Liu and Max Maizels

With technical advancements leading to ever more compact, portable, and less-expensive ultrasound units, pediatric urologists have increasingly incorporated ultrasonography into their office practices. Because it gives accurate information quickly, noninvasively, and without radiation, ultrasound has become the standard initial diagnostic evaluation of the pediatric urinary tract. Previously, we have shown the practical benefits of this modality[1–3] and now update this experience. In this chapter, we show how office ultrasound advances practice in the initial evaluation and follow-up of a variety of common pediatric urology scenarios.

Advantages of office ultrasonography in pediatric urology

Hydronephrosis, urinary tract infections, and wetting (or dysfunctional elimination) account for approximately 40% of office pediatric urology consultations. Traditionally, evaluation begins with a comprehensive office history and physical examination, with referral to radiology for a conventional ultrasound. In-office ultrasonography (IOUS) offers several advantages over this traditional approach. Including office ultrasound in the initial evaluation allows the urologist to make working diagnoses and management plans more quickly. It eliminates the need for unnecessary return visits and allows the opportunity to immediately build physician–patient–family interaction, thus reducing anxiety and providing a better understanding of the disease processes. Real-time explanation of the images by the urologist performing the examination solidifies this physician–patient bond. Because pediatric urologists have the clearest insight into the reason for the examination, they are able to sharply focus the examination. For example, bladder dynamics have a direct influence on the status of the kidneys. Recognizing this relationship, a pediatric urologist would be able to assess the kidneys both with a full and empty bladder, often providing more information than images performed by a non-urologist, where examination may not have included these images.

Performing in-office ultrasonography

A wide variety of portable, office-based ultrasound units are available commercially, ranging from large units requiring a wheeled cart to briefcase-sized units. In our practice, we use a toaster-sized sector scanner on a wheel cart at our hospital-based office and transport a briefcase-sized unit to satellite offices. We currently perform examinations with either a 5 or 7 MHz probe. For examination of the kidneys of older, larger patients, a low-frequency (3 or 5 MHz) probe is used because of its better tissue penetrance. A higher-frequency probe (7.5 or 10 MHz) is used to image closer objects such as the kidneys and bladders of younger children. Real-time images are displayed on the monitor and hard copies of the examination may be captured onto flash memory cards or printed directly onto thermal archival paper. Printed images are kept in the patient's charts, allowing the pediatric urologist quick access to the images on subsequent office visits.

A good ultrasound examination requires a calm, cooperative, and still patient. This can be challenging in the pediatric population. The process of preparing the child for the examination begins the moment the child enters the examination room. The child's clothes can be loosened without disrobing. We have adapted a videocassette recorder (VCR) to the examining platform to engage and distract children from fear of the hospital environment. Infants can be breast- or bottle-fed, allowing examination of a lulled child. Toddlers frequently fixate on the cartoons playing on the VCR. Engaging adolescents in simple word games may distract them. The routine of placing a small terry cloth protective towel over the patient's underwear becomes 'like an apron we use to help in the kitchen.' Applying ultrasound gel becomes 'like

suntan lotion we apply at the pool.' Furthermore, warming the gel prior to use with a self-heating unit keeps the child comfortable. Older children may be offered the opportunity of holding the transducer themselves. Very apprehensive children may be reassured by allowing their parents to apply the ultrasound gel, and the parent can hold the transducer as if the parent is performing the examination with the pediatric urologist manipulating the probe 'behind the parent.' Other useful tricks can be developed with some imagination.

Positioning the patient

Imaging of the kidneys

We typically begin office ultrasonography by positioning the child supine. Renal imaging in the supine position begins by placing the transducer anteriorly in the right or left subcostal region. The kidneys are imaged through an acoustic window provided by the liver (right kidney) or the spleen (left kidney). If the kidneys are not easily imaged subcostally, placing the transducer intercostally may help, although pushing here may be uncomfortable and derail the examination. Alternatively, the child may be placed in the lateral decubitus position. In a toddler or youth, this is accomplished by asking the supine child to grab his opposite elbow, which causes him to rotate his trunk himself. If the kidney is 'hidden' by an overlying rib, assuming the prone position will provide better images. The prone position also provides a more accurate measure of length, especially when the kidneys are sequestered under a rib. To image the kidney from the prone position, the transducer is placed along the line of a dorsal lumbotomy incision to provide a longitudinal image, or perpendicular to the line to provide a transverse image of the kidneys.[2] In younger and uncooperative children, office ultrasonography may be performed using a posterior approach, with the caregiver embracing the child. Sometimes, a child fearful of lying supine can be examined effectively while he is standing. Posterior views are obtained.

Imaging of the bladder and ureters

Imaging of the bladder is best performed with the child supine. The probe is placed above the pubic symphysis and aimed at the anus. Rotating the probe then provides a transverse or parasagittal view of the bladder. The ureters are also imaged if dilated. Typically, they are best seen 'behind' the bladder. Transverse bladder views show the ureters transversely. To image the ureters longitudinally, the probe is positioned parasagittally, aiming at the opposite half of the pelvis: thereby, the *right* parasagittal scanning of the bladder displays a sagittal view of a dilated *left* ureter and vice versa for the *right* ureter. In this view, assessment of the rectum for constipation, as well as imaging of the internal genitalia, may also be performed.

Common practical experiences of office ultrasonography in office pediatric urology

The kidney

IOUS is ideally suited to evaluate the kidneys for hydronephrosis, renal length, and duplication anomaly.

The normal kidney

The normal kidney is readily identified on sonography due to its sharp demarcation from surrounding structures. This sharp demarcation is due to the sonographic interface between the renal capsule and the surrounding perinephric fat. The shape of the kidney is ellipsoid in the longitudinal view (Figure 4.1). Renal length is measured using this view. The normal length of the kidney in the child is dependent on mul-

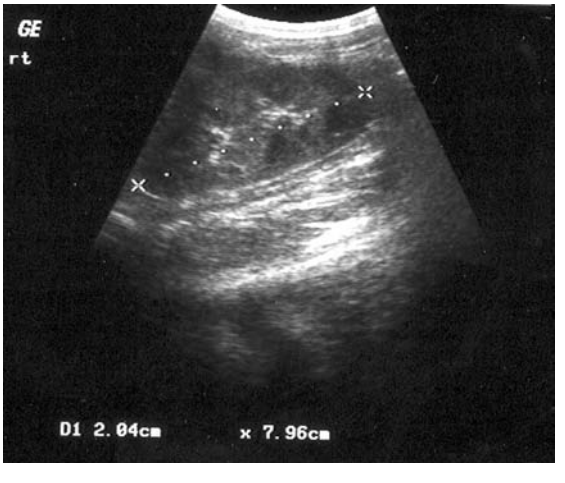

Figure 4.1 Office ultrasonography: normal kidney. Longitudinal view of a normal kidney of a 3-year-old boy was done for sibling screening of VUR. The renal length is 80 mm (normal mean 70 mm ± 10). The CEC is prominent because of its normal echogenicity. There is no hydronephrosis.

tiple variables, including the side of the kidney and the child's gender, height, weight, race, and age.[4] In the transverse view, the kidney appears ovular. The renal cortex is typically uniform in appearance and less echogenic than the liver and spleen. In children, the renal medullae (pyramids) are sonographically more prominent than in adults and appear as hypoechoic 'pockets' between the renal cortex and the renal sinus, like 'seeds in a watermelon'. Prominent renal pyramids can occasionally be confused with hydronephrosis, especially in the neonate. This confusion can be avoided by checking if the sonolucencies communicate with the pyelocaliceal architecture. Hypoechoic renal pyramids do not communicate with the renal pelvis, whereas dilated minor calices, evident in hydronephrosis, are confluent with the renal pelvis. The hilum is highly echogenic, often referred to as the central echogenic complex (CEC), containing the hilar vessels and fat.

Hydronephrosis

Office ultrasonography is the workhorse to approach diagnosis and management of hydronephrosis (HN). Hydronephrosis appears sonographically as sonolucent cavitation of the CEC. Hydronephrosis is graded according to the Society for Fetal Urology (SFU) classification system.[6] This classification system categorizes the pattern and extent of renal pelvic and caliceal dilatation, as well as renal parenchymal thickness (Table 4.1). Hydronephrosis detected on IOUS may be caused by ureteropelvic junction obstruction (UPJO), vesicoureteral reflux (VUR), obstructed upper pole moiety ureters (ectopic or ureterocele) of a duplex collecting system, high bladder pressure (e.g. neuropathic bladder), or lower urinary tract obstruction (e.g. posterior urethral valves). On the other hand, SFU grade 2 HN may represent a variant of normal as an extrarenal pelvis.

Sonographically evident renal pyelectasis

As prenatal ultrasound examinations become more common in obstetric practice, referrals to pediatric urologists to evaluate prenatally detected pyelectasis are becoming more frequent. The degree of prenatal pyelectasis that is clinically significant in predicting postnatal urologic significance has yet to be agreed upon. Thus, the term sonographically evident renal pyelectasis (SERP) has been coined in order to avoid the connotation of a disease process. In the postnatal evaluation of prenatally detected SERP, ultrasound examination is done after newborn discharge, at about 1 week of age. Office ultrasonography is commonly done during this follow-up. Common postnatal outcomes of SERP include spontaneous resolution, VUR, or UPJO. Even if IOUS demonstrates resolution of bilateral SERP, the child still has a 10–30% likelihood of occult VUR[6,7] (Figure 4.2). In this situation, office ultrasonography provides an opportunity for immediate counseling. Office ultrasonography also plays an important role in structuring management and follow-up of SERP.

Because of its convenience for performing serial examinations, office ultrasonography is an ideal modality to follow patients whose parents/family choose observational management for prenatally diagnosed SERP. In a portion of these patients, SERP will improve and the child will avoid unnecessary operative intervention (Case 1). When evaluating newborns for SERP, it is not important to delay ultrasound imaging for a few days after birth, as the initial postnatal ultrasound is unlikely to miss clinically significant hydronephrosis due to the relative

Table 4.1 SFU classification of hydronephrosis

Grade 0	No pelvic dilatation. Renal pelvis is empty. Echogenic hilar fat is not split by retained urine
Grade 1	Minimal pelvic dilatation (minimal retention of pelvic urine evident as a thin sonolucent stripe), no caliceal dilatation
Grade 2	Moderate pelvic dilatation (broad intrarenal sonolucent stripe, or an extrarenal pelvis). Major calices may be imaged but are not considered dilated. No minor caliceal dilatation
Grade 3	Large pelvis, dilated major calices, and dilated minor calices; normal parenchymal thickness
Grade 4	Exaggeration of Grade 3 *with* thin parenchyma

From Fernbach et al.[5]

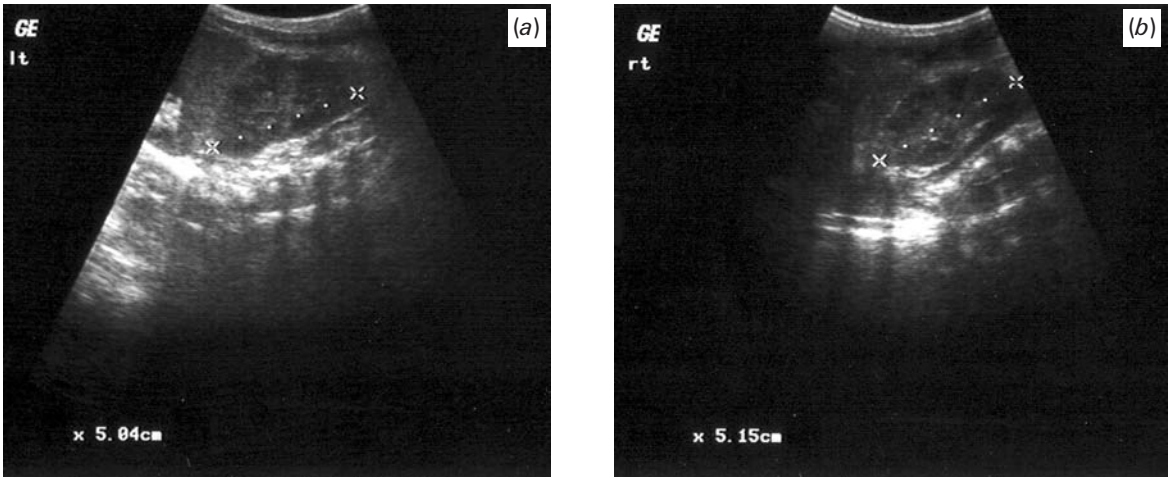

Figure 4.2 Office ultrasonography to follow-up fetal SERP. At 10 days old, the left (*a*) and right kidneys (*b*) are normal. These findings correlate with an 80% likelihood of a normal variant and 20% likelihood of VUR.

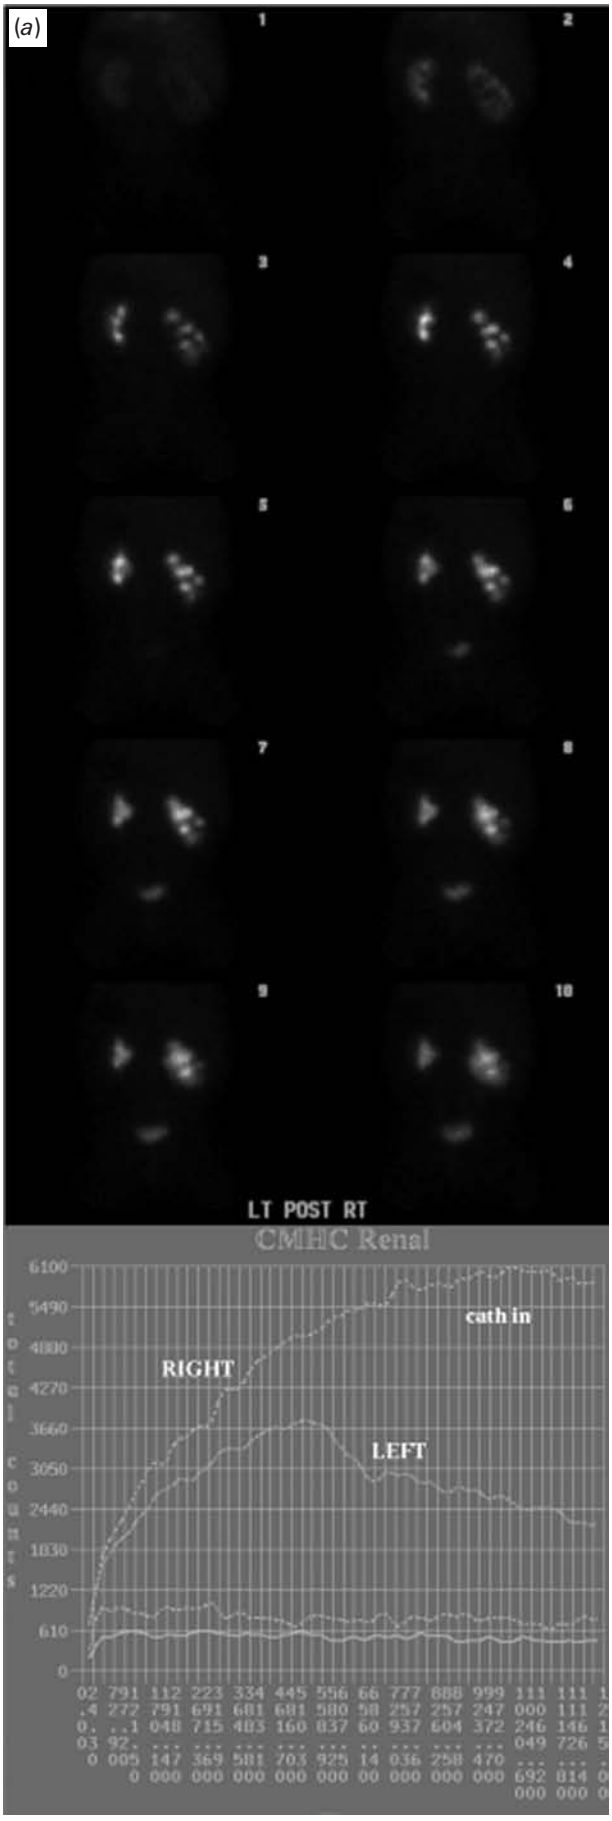
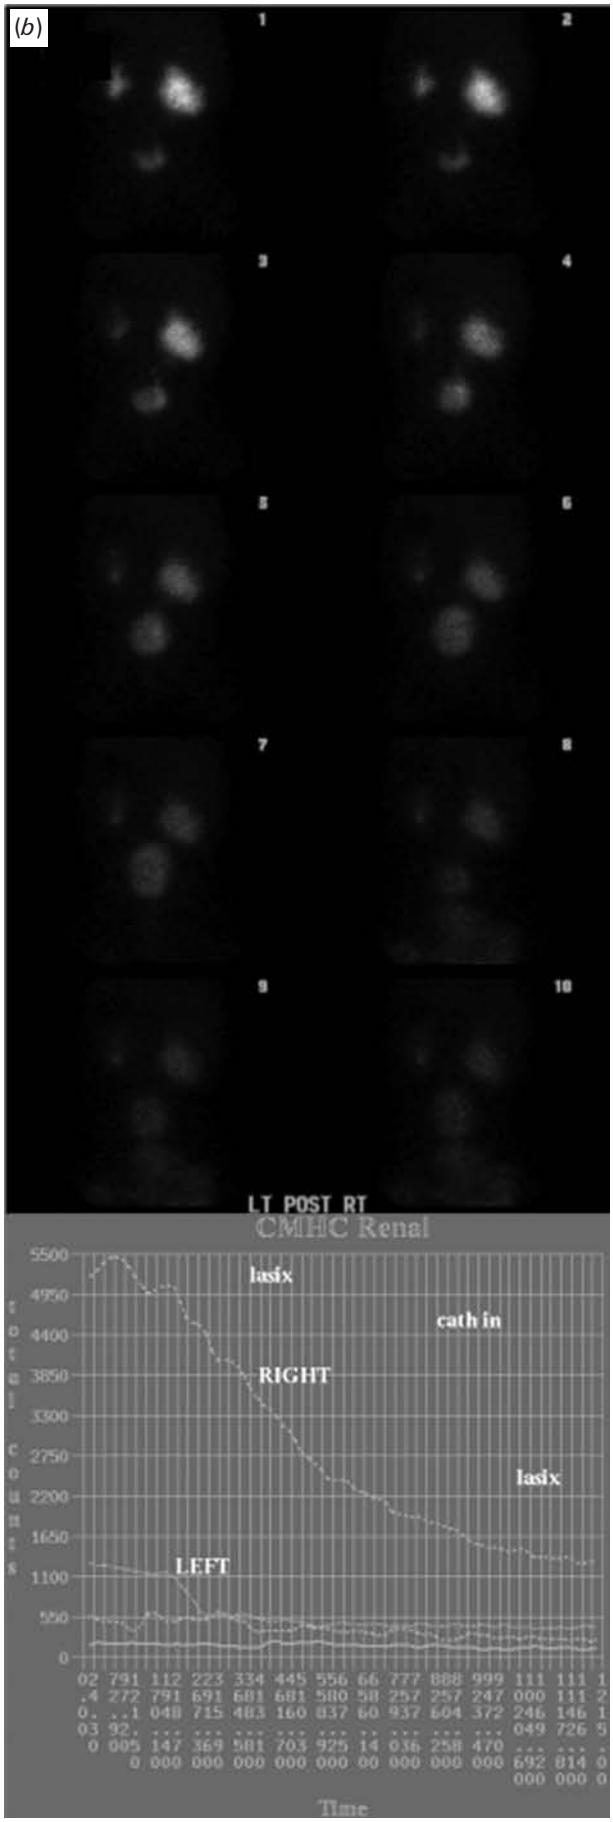
dehydration of the neonate, although it is very important to repeat the ultrasound at 3–4 months of age.[8,9] Such imaging can be conveniently and expediently done with office ultrasonography. Case 2 is a demonstrative illustration of the importance of delayed imaging for SERP by office ultrasonography.

Case 1. Office ultrasonography identifies resolution of fetal SERP (Figure 4.3).

Case 2. Office ultrasonography to follow-up premature ultrasonography for fetal hydronephrosis (Figure 4.4).



In addition to UPJO, SERP may also be caused by VUR. In order to evaluate for VUR, examination of hydronephrosis with both a full and empty bladder should be performed, as the status of the bladder directly impacts the appearance of the upper urinary tracts. Cases 3 and 4 demonstrate the utility of office ultrasonography in providing a more thorough evaluation of hydronephrosis by allowing the examiner to evaluate the upper urinary tracts with both a full and empty bladder. In both of these cases, the hydronephrosis improved with bladder emptying, and thus dilatation is more consistent with VUR than renal obstruction. Because of office ultrasonography, the diagnosis of VUR rather than UPJ obstruction was made correctly and without further radiographic testing. By referring patients to radiology for ultrasounds, the urologist is not in control of the examination and this often leads to imaging of the kidneys without regard to the status of the bladder fullness. In Case 5, not taking the state of bladder fullness into consideration may have led to an erroneous diagnosis of UPJ obstruction.



Case 3. Office ultrasonography shows fetal SERP likely related to VUR (Figure 4.5).

Case 4. Office ultrasonography shows the importance of considering the extent of bladder fullness on hydronephrosis (Figure 4.6).

Similarly, office ultrasonography provides an important adjunct to evaluate hydronephrosis during the performance of videourodynamics. When performing videourodynamics, precise imaging of the kidneys and assessment of the severity of the hydronephrosis are accomplished with office ultrasonography at varying degrees of bladder fullness as well as vesicular and detrusor pressures. This can provide the clinician with important information on the underlying etiology of the hydronephrosis. Office ultrasonography performed during videourodynamics is especially important when assessing patients born with posterior urethral valves (PUVs). Often, the clinical sequelae from PUV result in persistence of bilateral hydronephrosis, which may be due to either VUR and/or elevated bladder pressures.[11,12] Office ultrasonography is an effective modality to document changes in hydronephrosis, which may depend on the

Figure 4.3 Office ultrasonography identifies resolution of fetal SERP. Office ultrasonography was done to follow-up fetal hydronephrosis (HN). The newborn in hospital ultrasound shows SFU grade 4 HN (not shown). (*a*) Diuretic renogram shows preserved percent differential function in both kidneys with (*b*) $t_{1/2}$ drainage = 8.5 minutes. The parents chose observation rather than surgery.

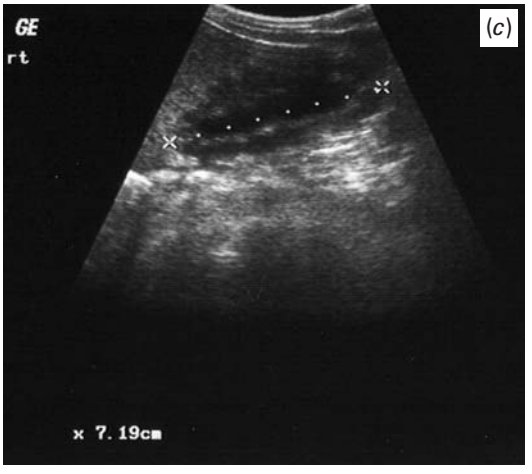

Figure 4.3 (*c*) Office ultrasonography follows up the hydronephrosis 2 months later. There is involution of the dilation to SFU grade 2 HN. Office ultrasonography is done for extended longitudinal follow-up.

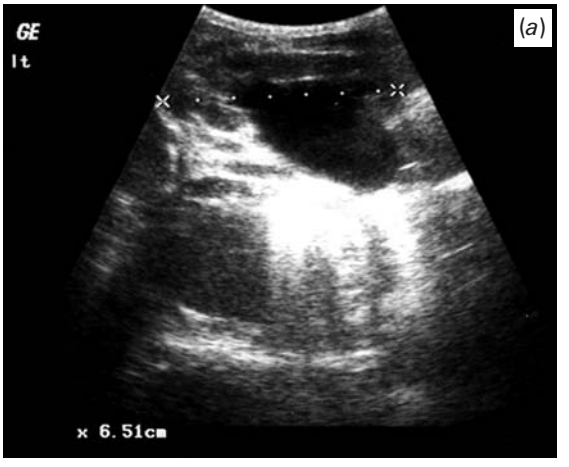

Figure 4.4 Office ultrasonography to follow-up newborn ultrasonography for fetal hydronephrosis (HN). Second trimester fetal ultrasound revealed hydronephrosis that progressed during the pregnancy. At term birth, the baby boy was healthy and the kidneys were not palpable. Ultrasonography was done prior to discharge and at this time did not show hydronephrosis. The family was informed that the problem had resolved. However, a urologic call back to the family was made, because the timing of this newborn ultrasound was viewed as premature. (*a*) Office ultrasonography was done at 1 month of age. The kidney is elongated (65 mm, predicted upper limit of normal = 65 mm)[5] with a large extrarenal pelvis and the dilated calices have become confluent, qualifying as SFU grade 3 HN. (*b*) Based on the office ultrasonography findings, a well-tempered renogram was done, showing preserved percent differential function and (*c*) delayed drainage of isotope.

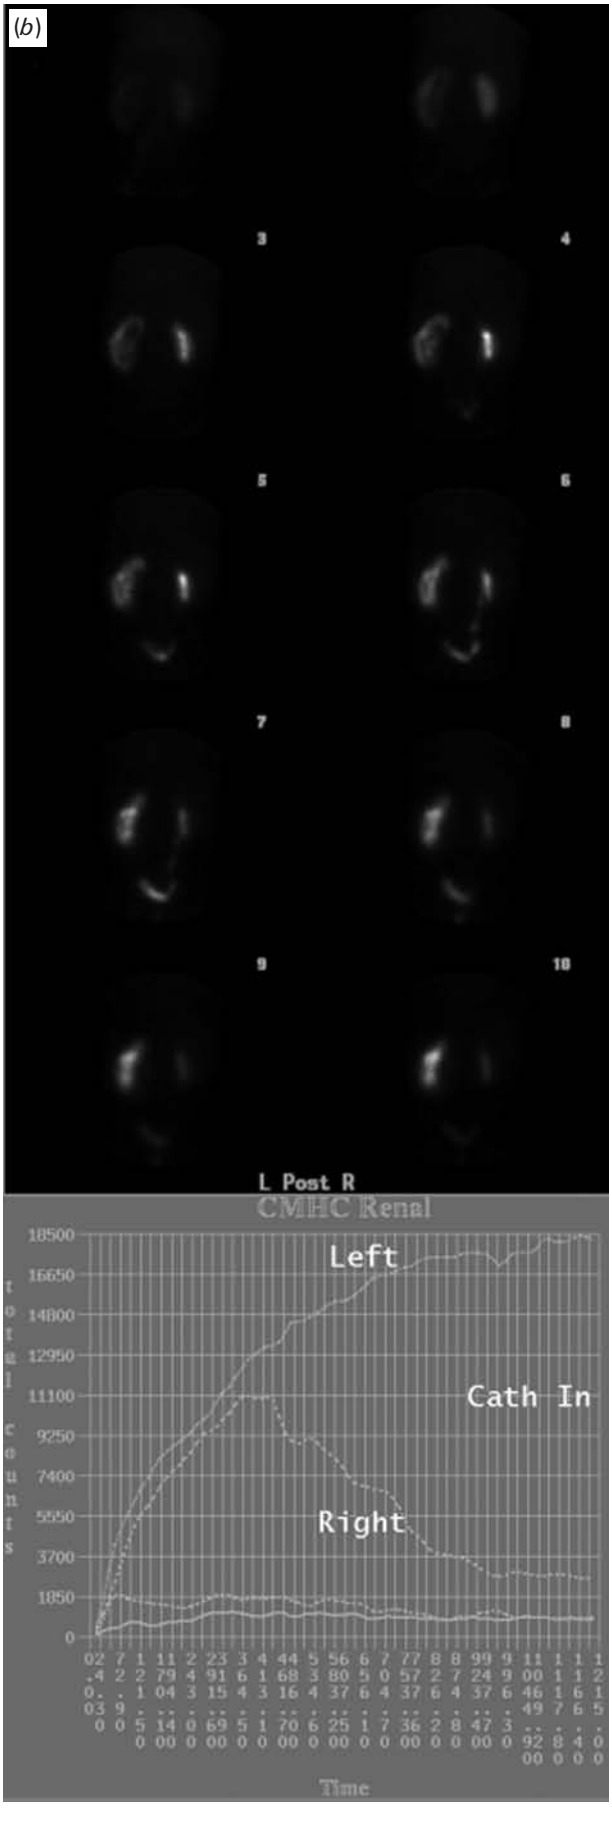
level of bladder pressure and fullness. This helps to identify patients that would benefit from institution of clean intermittent catheterization to protect their upper tracts.

Case 5. Office ultrasonography is an additional dimension to videourodynamic testing (Figure 4.7).

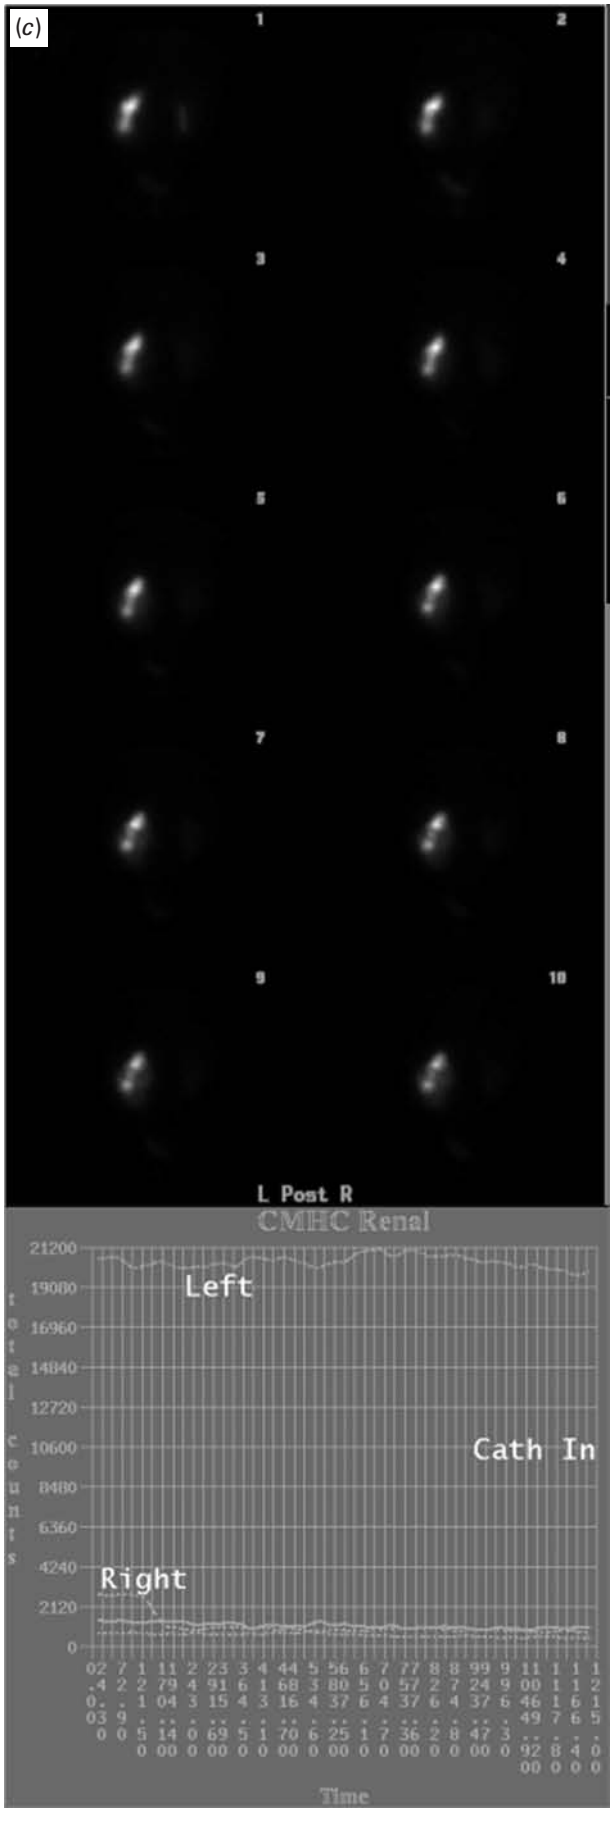
Anatomic anomalies

In addition to its role in evaluating hydronephrosis, office ultrasonography is useful to diagnose a variety of anatomic anomalies. Anomalies that can be readily detected by office ultrasonography include duplex collecting systems, multicystic dysplastic kidney, and renal dysplasia manifested by increased echogenicity, failure of renal growth, or renal asymmetry. These anatomic anomalies may be detected serendipitously on evaluation for common pediatric urologic complaints, such as enuresis.

Case 6. Duplex collecting system (Figure 4.8).



Multicystic dysplastic kidney



The examination for follow-up of fetal multicystic dysplastic kidney (MCDK) is initiated in the newborn by ultrasound examination, which may be done by office ultrasonography. Ultrasound features typical of MCDK involve enlarged kidney without reniform shape but with echogenic parenchyma and multiple non-communicating cysts of diverse sizes. The differential diagnosis of MCDK should include the possibility of UPJO. The main differentiating feature is that there is contiguity between an obstructed pelvis and dilated calices seen in UPJO but no contiguity seen in MCDK. Office ultrasonography is useful to follow the dilated kidney for involution, which would then solidify the diagnosis of MCDK, as obstructed non-dysplastic kidneys do not involute.

Case 7. Figure 4.9.

The echogenic kidney

Office ultrasonography is an ideal way to follow-up echogenic kidneys. Normal kidneys are typically less echogenic than the liver and spleen. When the echogenicity of the kidney is increased, suspicion of impaired renal function must be entertained.[13,14] Echogenic kidneys have been commonly found in the contralateral kidneys of patients with MCDK.[15] Although the significance of renal echogenicity has yet to be determined, the growth and appearance of the contralateral kidney in patients with MCDK should be followed closely and this may be expeditiously accomplished with office ultrasonography.

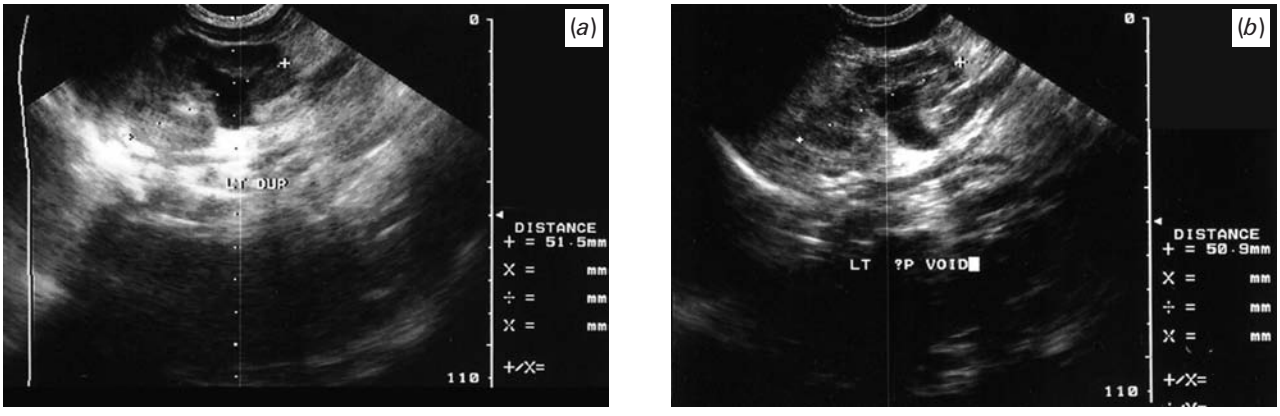

Figure 4.5 Office ultrasonography shows fetal SERP likely related to vesicoureteral reflux (VUR). (*a*) The child's kidney on initial examination shows an extrarenal pelvis (SFU grade 2) and is not consistent with obstruction. (*b*) By serendipity, the child voided during the office ultrasonography and the kidney immediately shows a subjective impression of new, increased dilation of the pelvis. These findings are consistent with VUR.

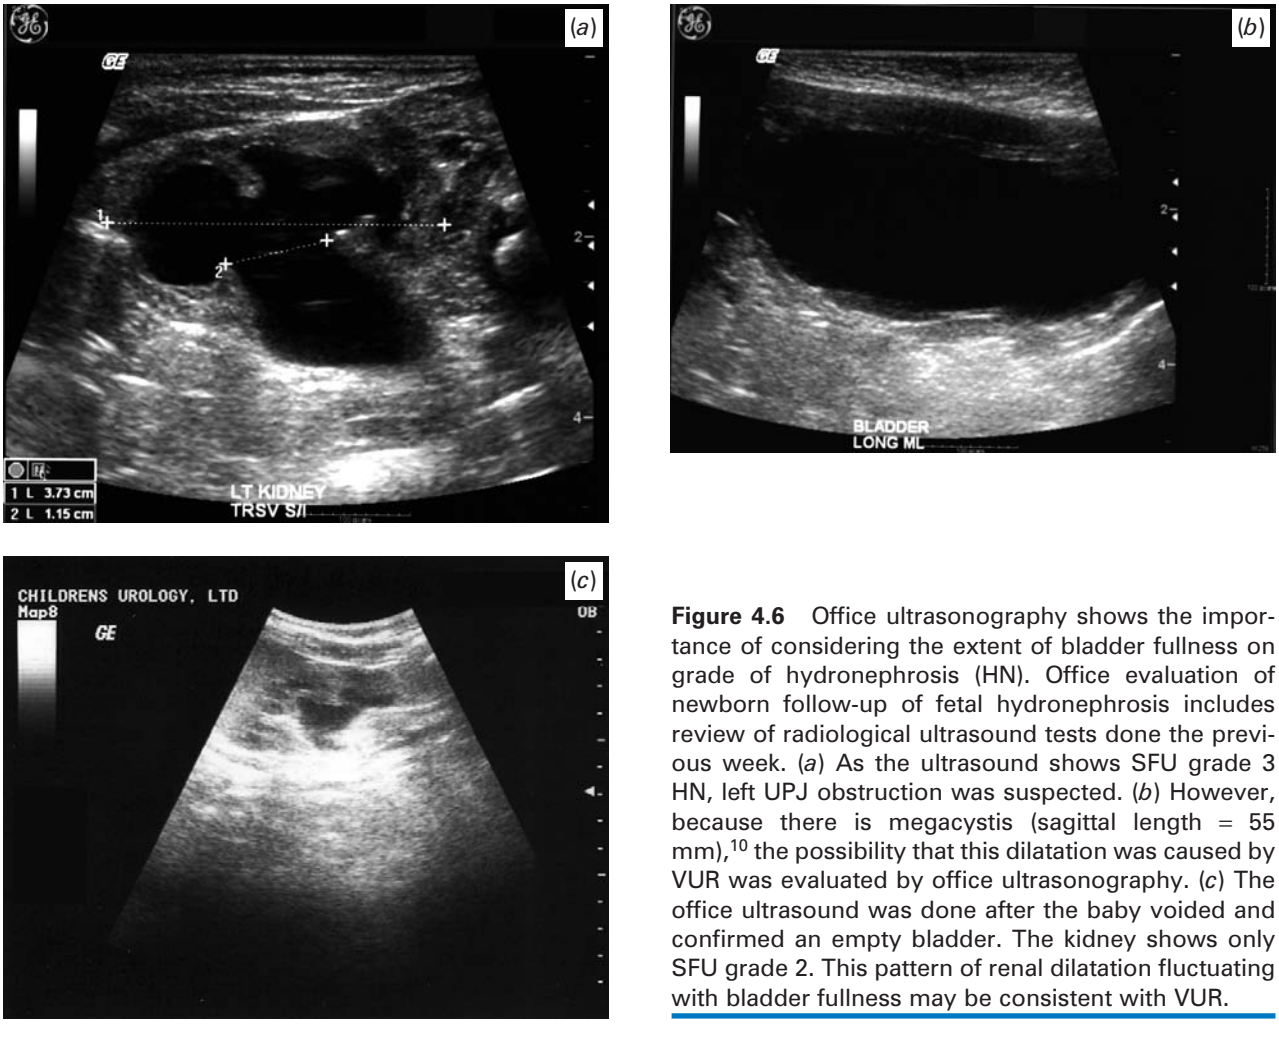

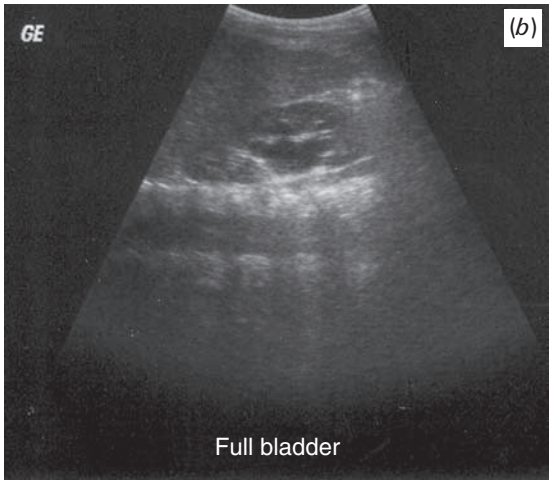

Figure 4.6 Office ultrasonography shows the importance of considering the extent of bladder fullness on grade of hydronephrosis (HN). Office evaluation of newborn follow-up of fetal hydronephrosis includes review of radiological ultrasound tests done the previous week. (*a*) As the ultrasound shows SFU grade 3 HN, left UPJ obstruction was suspected. (*b*) However, because there is megacystis (sagittal length = 55 mm),[10] the possibility that this dilatation was caused by VUR was evaluated by office ultrasonography. (*c*) The office ultrasound was done after the baby voided and confirmed an empty bladder. The kidney shows only SFU grade 2. This pattern of renal dilatation fluctuating with bladder fullness may be consistent with VUR.

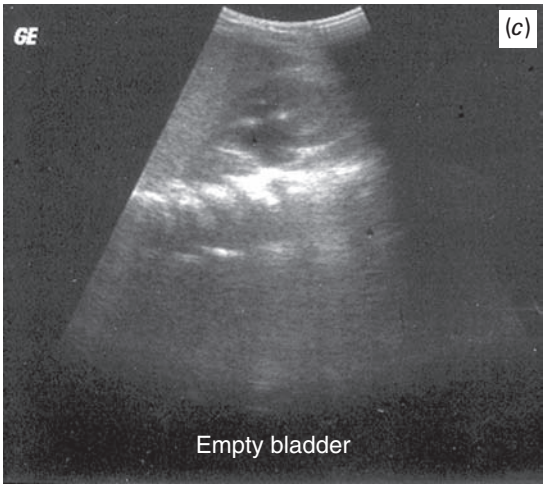

Figure 4.7 Office ultrasonography is an additional dimension to videourodynamic testing. A 9-month-old boy is status post-newborn ablation of posterior urethral valves (PUVs). Bilateral hydronephrosis persists. (*a*) The cause for the persistent dilatation was not persistent PUV, as the urethra is open on VCUG, or reflux, as the cystogram is normal. Office ultrasonography is done simultaneous with videourodynamics to assess if bladder filling increases bladder pressure and so accounts for the renal dilatation. Office ultrasonography shows stable SFU grade 3 of the right kidney with the bladder both (*b*) full and (*c*) empty. Bladder pressures were <40 cmH_2O. The baby has continued to thrive with no further treatment. As the urologic testing is normal, it is likely the hydronephrosis will gradually resolve over the next 2 years, though serial follow-up studies are mandatory.

Case 8. Office ultrasonography shows improved echogenicity of the contralateral kidney (Figure 4.10).

In addition to increased echogenicity, impaired growth of a kidney is also suspicious for irreversible damage. Office ultrasonography is used commonly to follow the growth of these 'at-risk' kidneys, as well as following the growth of the contralateral kidney in patients with MCDK.[16] By keeping the images conveniently available in the patient's chart, quick review of past examinations for an assessment of renal growth can be readily done. Confirmation of renal function should then be done with renal scintigraphy as indicated.

Case 9. Renal growth (Figure 4.11).

In addition to aiding in the diagnosis and evaluation of common pediatric urology problems, office ultrasonography is invaluable to follow patients after urologic surgery. Office ultrasonography aids in the serial assessment of the postoperative status of the kidney and/or bladder and helps monitor for possible surgical complications. We use office ultrasonography routinely to follow patients after:

- pyeloplasty, to assure there is gradual reduction in grade of hydronephrosis
- antireflux surgery, to assure the resolution of hydronephrosis and proper bladder emptying
- ablation of PUVs, to assure improvement in the degree of bladder and kidney dilatation.

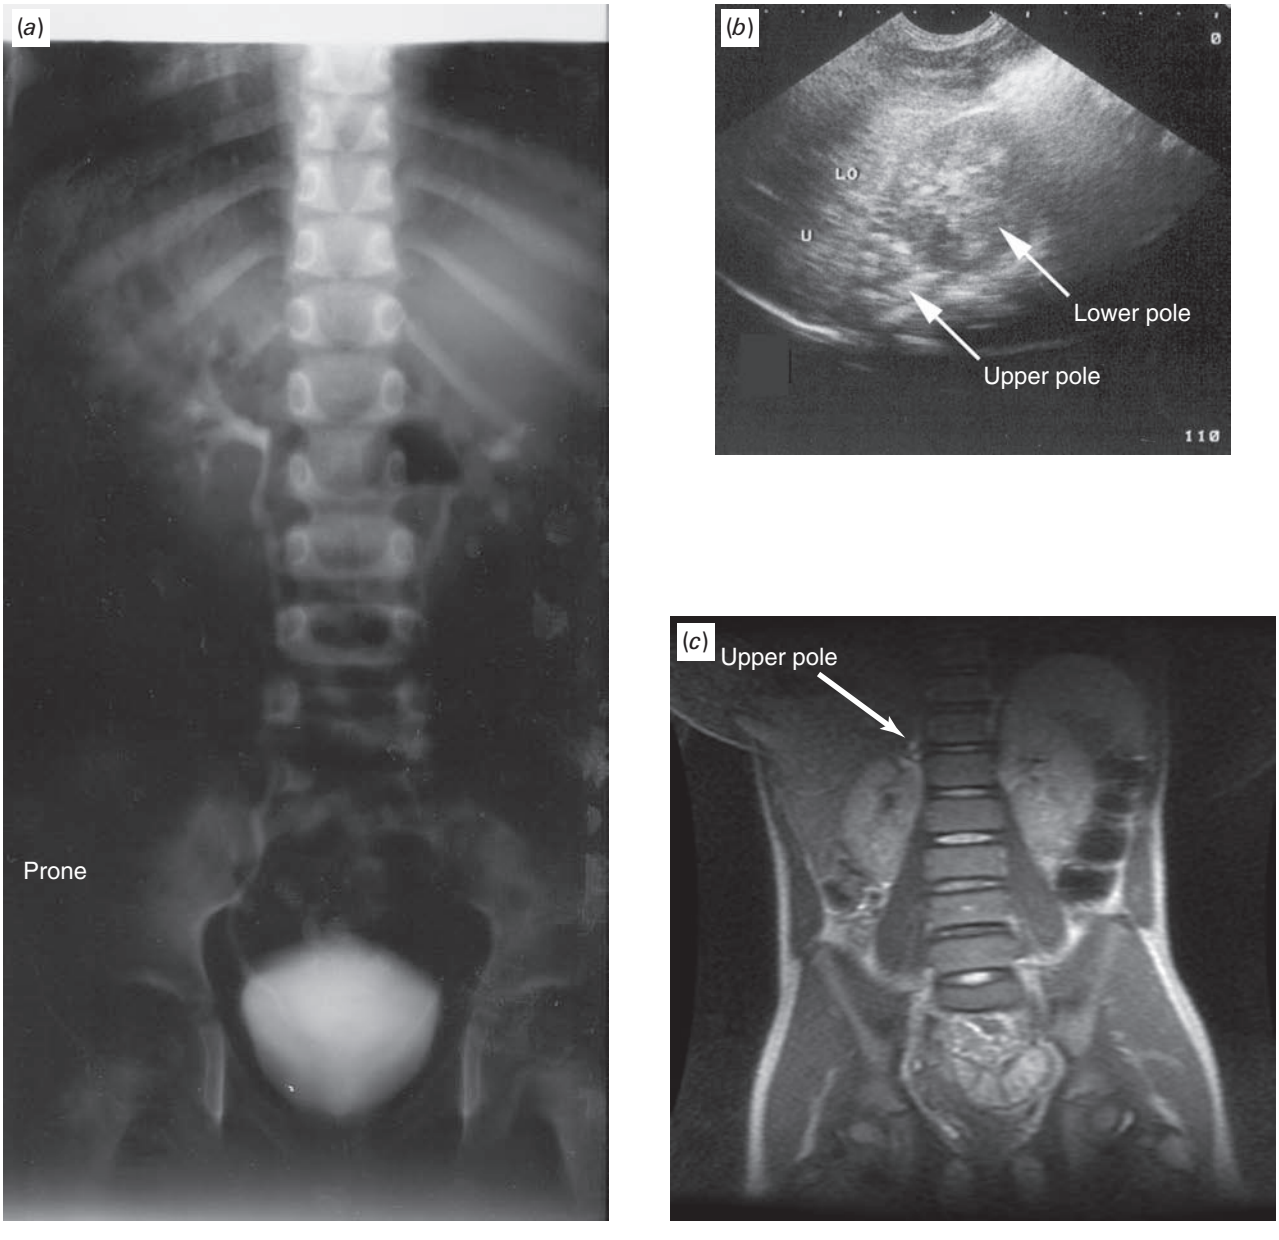

Figure 4.8 Duplex collecting system. A 5-year-old girl is evaluated in the office for diurnal enuresis. (*a*) IVP (prone view) done previously is interpreted to be normal. Review of the study suggests an absent *right* upper pole. (*b*) Office ultrasonography is done to answer this concern and shows a bifid pattern consistent with renal duplication. (*c*) The office ultrasound finding prompted an MRI, which showed renal duplication and ectopic ureter. An ipsilateral ureteroureterostomy was performed and the enuresis resolved. This case exemplifies the use of office ultrasonography to evaluate common outpatient pediatric urologic complaints, including enuresis. By performing office ultrasonography at the time of the visit, the suspicion of a duplex collecting system was pursued and led quickly to a more conclusive radiographic study (MRI), which was diagnostic.

Postpyeloplasty

In the setting of pyeloplasty, office ultrasonography plays an important role in monitoring the success of the procedure. Office ultrasonography is used to check for resolution of hydronephrosis, which is typically seen within 2 years postoperatively, and normalization of elongated kidney length, which is typically seen within 5 years postoperatively. Postpyeloplasty imaging with office ultrasonography showing stabilization or improvement of hydronephrosis provides reasonable assurance of a successful procedure.[17,18] Should office ultrasonography show upgrading of hydronephrosis, especially after the ini-

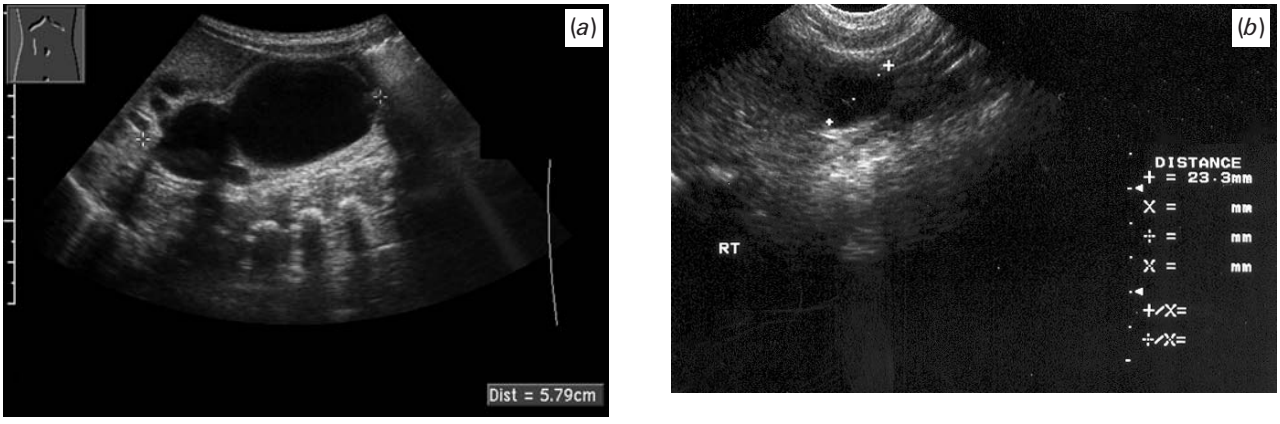

Figure 4.9 Office ultrasonography shows involution of MCDK. Fetal ultrasounds of the right kidney have shown an MCDK. (*a*) The newborn ultrasound confirms this finding. (*b*) Office ultrasonography is performed 1 year later for follow-up. There is involution of the right kidney, thereby confirming the diagnosis of MCDK.

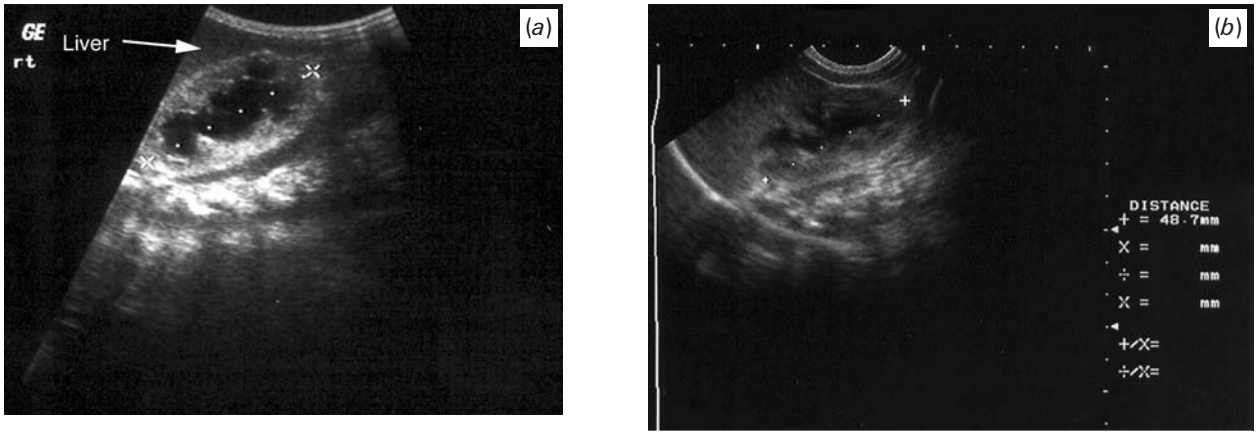

Figure 4.10 Office ultrasonography to follow-up echogenic, hydronephrotic kidney. (*a*) This newborn boy has renal parenchyma more echogenic than the liver. There is SFU grade 3 hydronephrosis (HN). The contralateral kidney is an MCDK (not shown). Furthermore, his older sister showed bilateral UPJ obstruction with renal hypoplasia. (*b*) Office ultrasonography at 3 months follow-up shows the right kidney is isoechoic with the liver and there is less hydronephrosis (SFU grade 2 HN). Further management includes surveillance office ultrasonography.

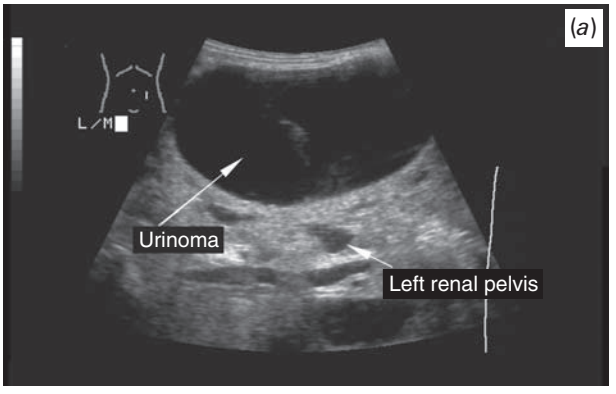
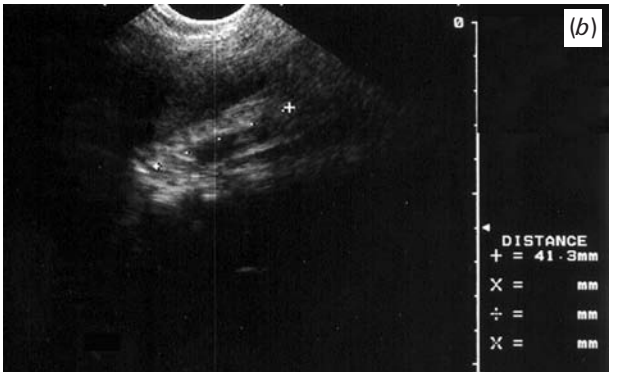
tial ultrasound at 1 month, a more complete evaluation with either a diuretic renogram or a retrograde pyelogram is in order. We perform office ultrasonography to check for a gradual decline in hydronephrosis postpyeloplasty at 1 month, 6 months, 1 year, 2 years, and 5 years postoperatively.

Case 11. Figure 4.12.

Postdetrusorrhaphy



Success rates for surgical repair of VUR are approximately 80–99%.[19] The potential complications of detrusorrhaphy include persistent VUR, new-onset contralateral VUR, and obstruction at the UV junction. Office ultrasonography plays an important role in monitoring the kidneys for hydronephrosis, a sign of these potential complications, especially UVJ obstruction.

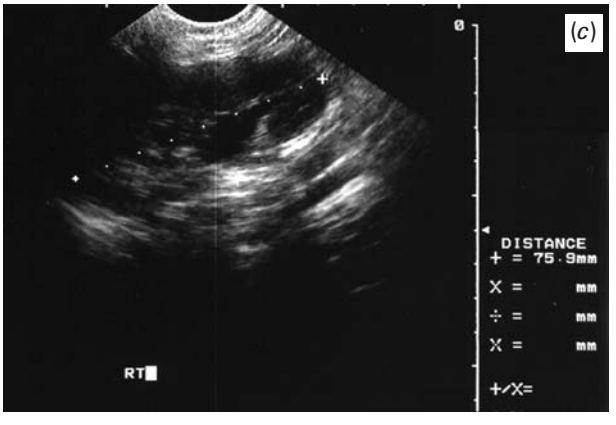


Case 12. Figure 4.13.

The ureters

In addition to visualizing the kidneys, office ultrasonography may be used to image the ureters. Normal ureters are not dilated, and thus are not imaged. However, dilated ureters are readily identified. Dilated ureters may accompany hydronephrosis. When ureteral dilatation is present without hydronephrosis, the differential diagnosis includes VUR and primary megaureter (non-obstructive, non-refluxing).

Case 13. Non-obstructive, non-refluxing primary megaureter (Figure 4.14).



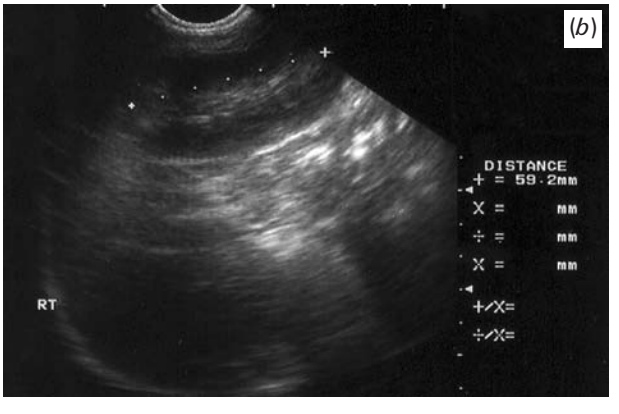


Figure 4.11 Office ultrasonography used to follow renal growth. Fetal diagnosis of bladder neck obstruction proved to be anterior urethral valves at newborn endoscopy. (*a*) The left renal urinoma almost completely effaced the kidney. The child voided well after valve ablation. Office ultrasonography at 1 year of age, shows (*b*) the left kidney is echogenic and is smaller than (*c*) the right kidney. It is likely that the left kidney is small due to the damaging effects of fetal urinoma, and the right kidney is hypertrophied to compensate for the small left kidney.

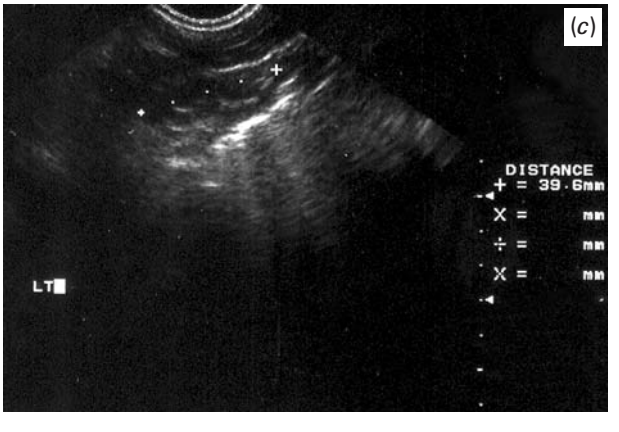

Figure 4.12 (*a*) Pyeloplasty was done for UPJ obstruction. (*b*) By 1 year postoperatively, the office ultrasound reveals only SFU grade 2 hydronephrosis (HN) and (*c*) only SFU grade 2 HN in the right kidney.

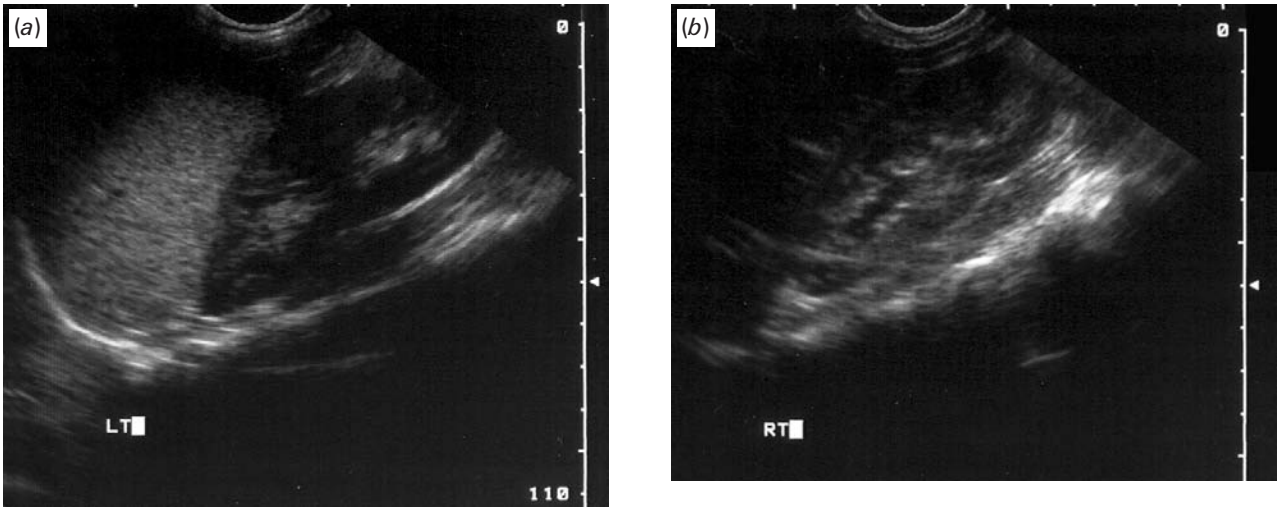

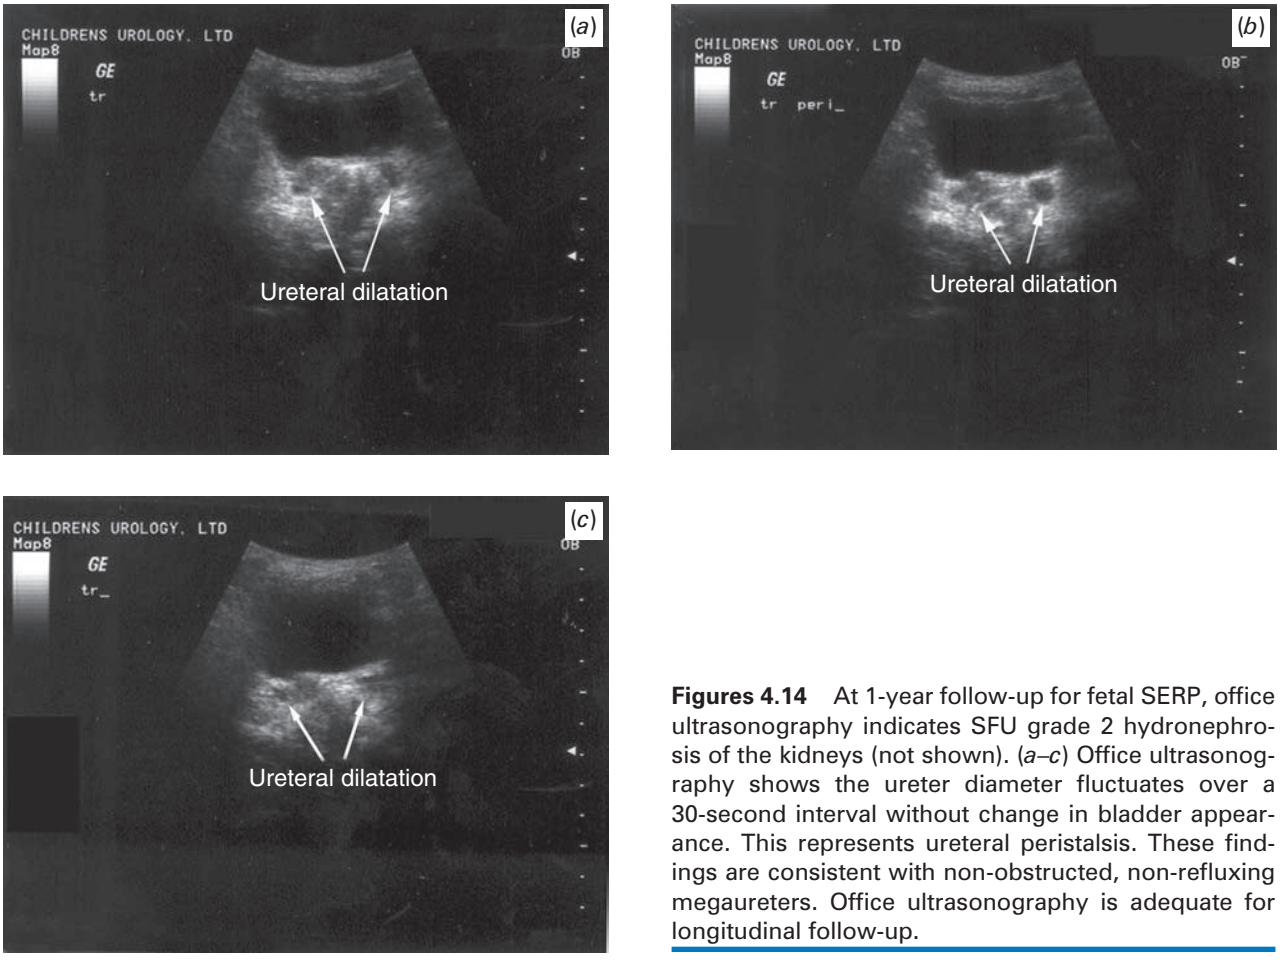

Figure 4.13 A 6-year-old girl with breakthrough febrile UTIs and VUR underwent bilateral detrusorrhaphy. (*a* and *b*) Two weeks postoperatively, office ultrasonography shows normal kidneys without hydronephrosis and the bladder is empty postvoid (not shown).

Figures 4.14 At 1-year follow-up for fetal SERP, office ultrasonography indicates SFU grade 2 hydronephrosis of the kidneys (not shown). (*a–c*) Office ultrasonography shows the ureter diameter fluctuates over a 30-second interval without change in bladder appearance. This represents ureteral peristalsis. These findings are consistent with non-obstructed, non-refluxing megaureters. Office ultrasonography is adequate for longitudinal follow-up.

The bladder

Office ultrasonography provides a reliable and easy way to assess the bladder. We have used office ultrasonography to assess megacystis, completeness of bladder emptying, and for follow-up after endoscopic ureterocele incision.

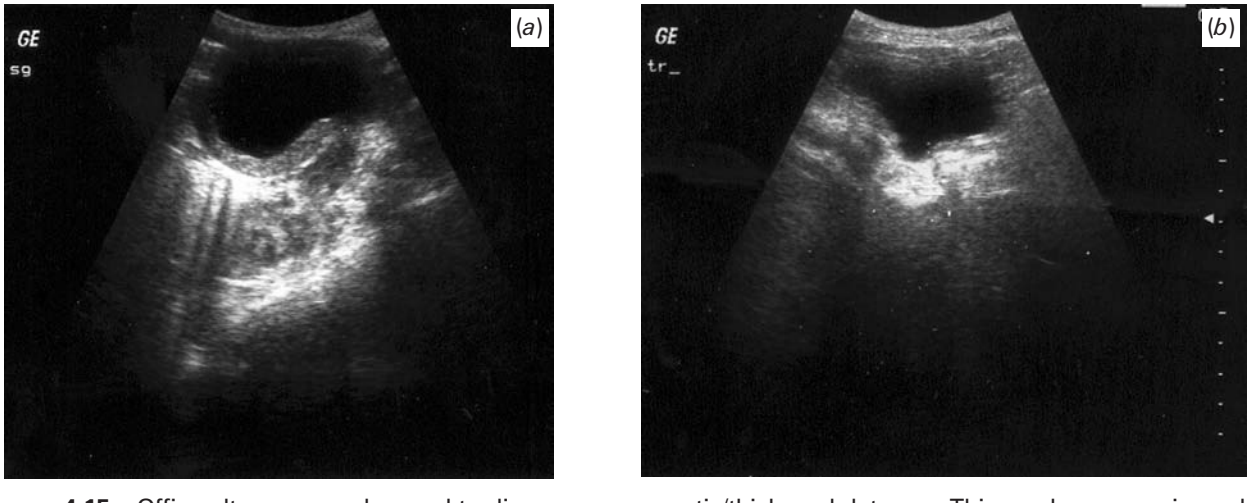
The normal bladder

A bladder is best assessed when partially filled or full. The normal bladder is smooth-walled and symmetrical and filled with echolucent urine without any other internal echoes. However, urine within a neonate's bladder may be echogenic. This has been attributed to the elevated levels of Tamm–Horsfall protein. The normal capacity of the bladder may be estimated by the formula:[20]

$$\text{Bladder volume (ounces)} = \text{Age (years)} + 2$$

Office ultrasonography may be used to measure the detrusor thickness while evaluating children with voiding dysfunction. The thickness of the detrusor appears distinct in the sonographic examination of the bladder. The normal thickness of the bladder wall is dependent on the extent of bladder fullness. Normative values have been described; however, no consensus has been reached.[21–24] Office ultrasonography, though, continues to be useful in following the course of bladder treatments.

Case 14. Office ultrasonography used to diagnose megacystis/thickened detrusor (Figure 4.15).



Ureterocele

Ureteroceles are commonly detected during the evaluation of hydronephrosis. The diagnosis may be missed when other causes of hydronephrosis, such as reflux, are also present. Careful evaluation of the bladder with ultrasound remains the best imaging modality to diagnose ureteroceles. Patience during the ultrasound to permit the bladder to empty as the infant voids allows imaging during various stages of bladder fullness. This is important, as varying levels of bladder fullness influence the ease of detecting ureteroceles. For example, a full bladder may compress the ureterocele and make the ureterocele more difficult to identify. Office ultrasonography permits the examining urologist to avoid this potential pitfall by performing ultrasound at differing levels of bladder fullness.

Case 15. Figure 4.16.

Care of myelomeningocele patients

Care of myelomeningocele patients requires close follow-up in order to prevent urinary tract deterioration. Office ultrasonography is an effective and expedient tool to monitor these patients. Office ultrasonography can identify patients at risk of upper tract deterioration due to abnormal bladder dynamics and prompt the institution of more individualized blad-

Figures 4.15 Office ultrasonography used to diagnose megacystis/thickened detrusor. This newborn experienced a cerebral hemorrhage and secondary neurogenic bladder. The VCUG showed an enlarged bladder and bilateral VUR. Intermittent bladder catheterization was instituted along with medical therapy for the cerebral hemorrhage. Catheterization was tapered. (*a*) After hospital discharge, office ultrasonography shows a thickened detrusor. (*b*) After 6 months, the detrusor thickness resolved, and the diaper pattern suggested good bladder emptying.

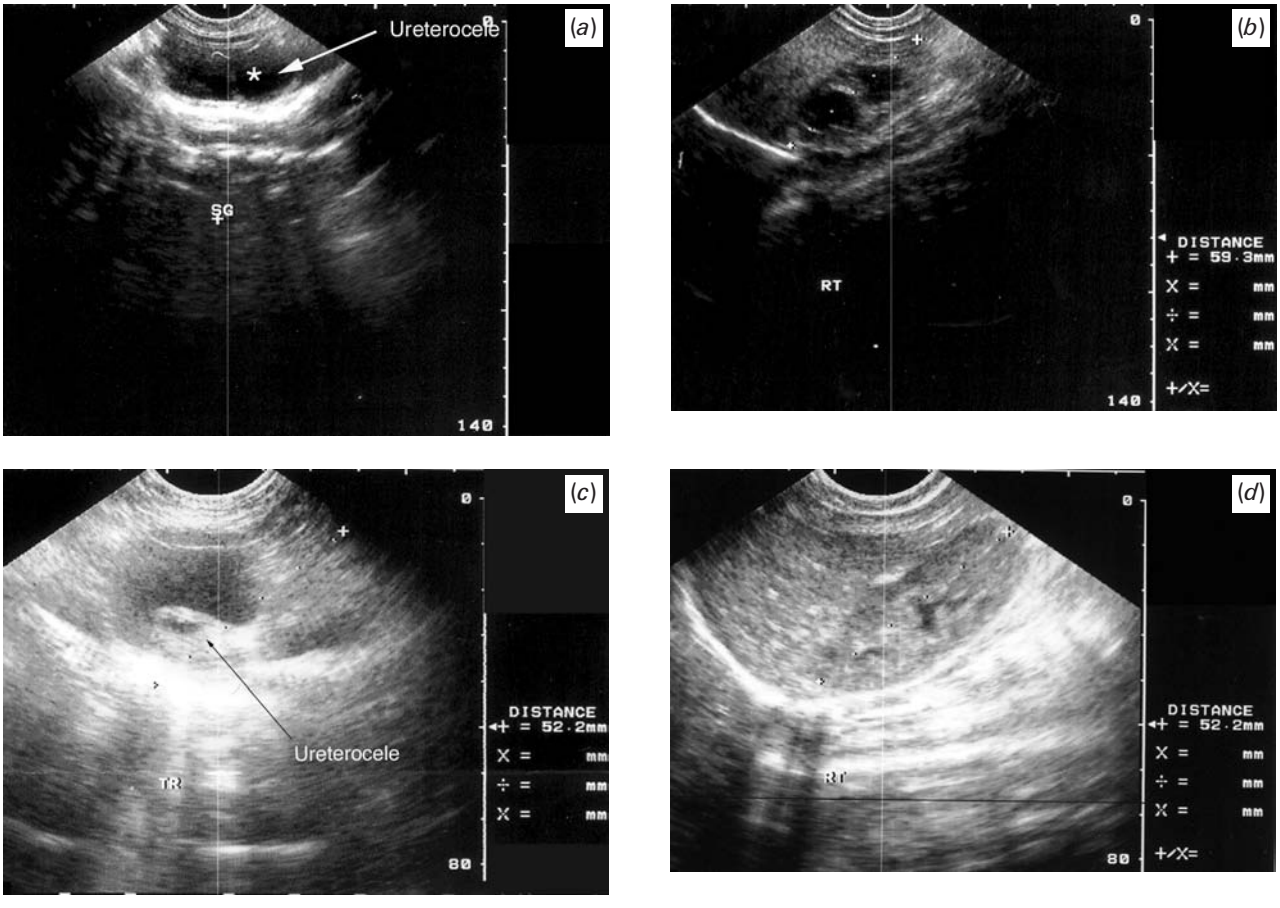


Figure 4.16 Office ultrasonography monitors postoperative course after incision of newborn ureterocele. A 2-month-old girl presented with a history of fetal diagnosis of SERP. Reports of follow-up radiographic imaging documented right hydronephrosis and a normal bladder. The VCUG report documented right VUR. On the day of outpatient evaluation, there were no hard copies available to review. (*a*) Office ultrasonography was done and showed a previously unrecognized ureterocele, and (*b*) a duplication anomaly that accounted for the reported hydronephrosis. Because of these office ultrasonography findings, transurethral incision of the ureterocele was done the following day. Postoperative follow-up with office ultrasonography shows (*c*) decompression of the ureterocele and (*d*) reduction in hydronephrosis.

der treatment.[25] Office ultrasound may also be easily used to monitor myelomeningocele patients after complex urinary reconstruction for bladder capacity as well as complications such as renal calculi formation.

Case 16. Office ultrasonography to diagnose bladder calculi (Figure 4.17).

Evaluation of bladder emptying

Office ultrasonography provides a powerful tool to evaluate patients with dysfunctional voiding and recurrent urinary tract infection. The ability to image the bladder before and immediately after voiding allows the pediatric urologist to determine the child's bladder-emptying capabilities. The volume of urine within the bladder is often automatically determined by the ultrasound machine, using the formula:[26]

$$\text{Volume} = 0.52 \times \text{length} \times \text{width} \times \text{height}$$

In children, the residual volume of urine in the normal bladder should be less than 10% of the age-specific expected bladder capacity.

Case 17. Office ultrasonography to evaluate bladder emptying/postvoid residual (Figure 4.18).

Similarly, office ultrasonography may be included in the work-up for dysfunctional elimination syndrome (DES) by checking for a fecal plug, a characteristic feature of children with constipation. One of the most difficult histories to obtain in the evaluation of a child with enuresis is an accurate assessment of bowel function. Klijn et al[27] have correlated the ultrasonic measurement of rectal diameter to the clinical diagnosis of constipation in children, and advocate the use of

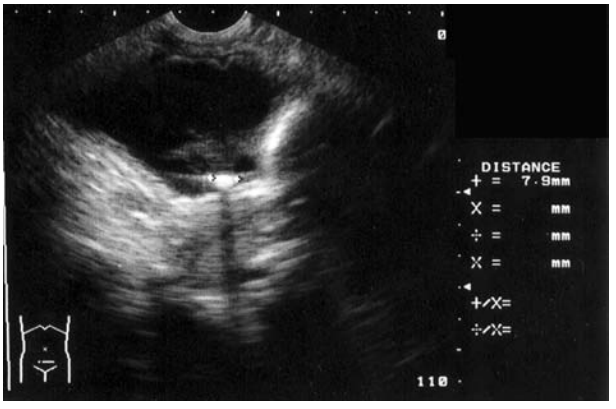

Figure 4.17 Office ultrasonography to diagnose bladder calculi during outpatient follow-up of a 7-year-old girl with myelomeningocele who is status post-bladder augmentation for recurrent episodes of UTI and bladder calculi. The office ultrasonography shows an echogenic focus at the posterior wall of the bladder with acoustic shadowing, most likely a bladder calculus. Based on this office finding, cystoscopy confirmed the calculus, which was retrieved endoscopically. (Courtesy of Dr Kenneth A Kropp, Toledo, Ohio.)

ultrasound to assist in making this diagnosis. The office ultrasonography in a 7-year-old girl with persistent enuresis, recurrent UTIs, and a large fecal plug is shown (Case 18).

Case 18. Office ultrasonography shows a fecal plug in the evaluation of a child with DES (Figure 4.19).

Office ultrasonography: reliability, credentialing, and coding

We have been performing office ultrasonography as part of the urologic evaluation of patients since 1986.

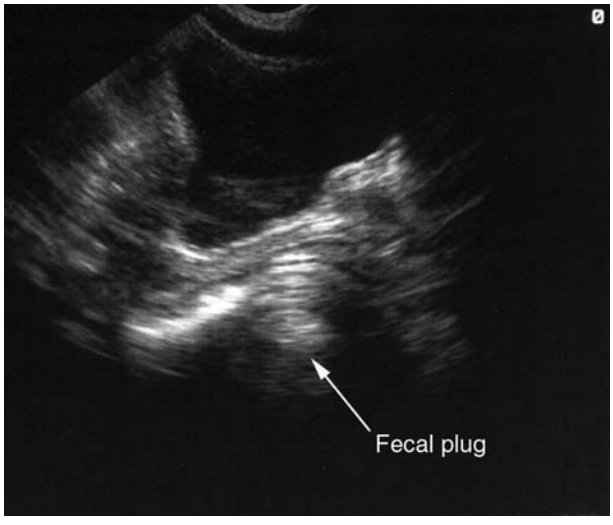

Figure 4.19 Office ultrasonography shows a fecal plug in the evaluation of a child with dysfunctional elimination syndrome (DES). This 7-year-old girl presented for evaluation of wetting and urinary infection. Neither the child nor the parents were aware of symptoms of constipation. The office ultrasound shows a large fecal plug posterior to the bladder. A bowel program was initiated as part of the global approach to the treatment of DES.

In an initial study of the reliability of office ultrasonography, Maizels et al demonstrated that office ultrasonography had a 98% sensitivity and an 82% specificity when compared with clinical outcomes or excretory urogram (IVP).[1] As ultrasound machines become more common in the office setting, urologists are becoming more and more comfortable with the performance of urologic ultrasound. Vesey et al[28] found that urologist-operated ultrasounds were accu-

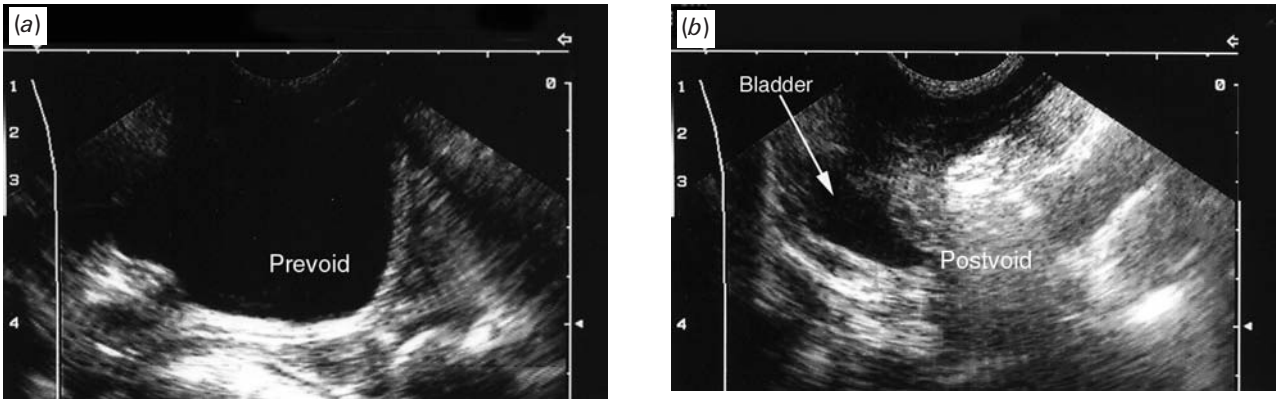

Figure 4.18 Office ultrasonography to evaluate bladder emptying/postvoid residual. The radiographic ultrasound of this 8-year-old girl with recurrent afebrile UTIs shows normal kidneys. On referral, because the family mentioned the girl voided infrequently, an office ultrasound was done. Even though the girl did not sense the need to void, the office ultrasonography shows a remarkably distended bladder (*a*). After prompting, she voided 40 ml, and the postvoid office ultrasonography shows the bladder is decompressed (*b*). The office ultrasonography examination prompted a program of conditioned voiding to decrease the risk of urinary infection.

rate and reliable when compared with ultrasounds performed by radiologists. Nevertheless, from time to time, there may be benefit for referral to radiology of cases for a second opinion. The American Urological Association (AUA) in conjunction with the Residency Review Committee is responsible for ensuring that urologists are sufficiently educated and qualified in performing ultrasound examinations through residency training programs. Successful completion of board certification by the AUA is evidence of the urologist's proficiency in performing ultrasound examinations.[29]

Ultrasound examination is coded according to the Current Procedural Terminology (CPT) 5-digit code. Depending on the examination performed and the extensiveness of the examination, the appropriate 5-digit code is applied. Record keeping to completely document the examination must be done.

Conclusion

In this chapter, we have demonstrated the advantages of performing office ultrasonography. During an office visit, office ultrasonography significantly adds to information needed to extend care. As urologic training programs absorb office ultrasound into their curricula, pediatric urologists will incorporate office ultrasonography as an inherent aspect of pediatric urologic evaluation.

Pediatric renal nuclear medicine

5

Martin Charron

Technique considerations

In children, radionuclide renal studies are widely used to evaluate various disorders. When combined with an ultrasound study, the two usually give a complete assessment of the state of the kidneys. In neonates with compromised renal function, the nuclear study is the most accurate method for determining the function of each or both kidneys.

Serial assessment of renal function is important to pediatric nephrology/urology, particularly in children with hydronephrosis, vesicoureteral reflux, after acute pyelonephritis, and in those who may require evaluation postoperatively. The decision of whether to do a nephrectomy or a reconstructive procedure may be a difficult one, especially in the child whose contralateral kidney is already jeopardized. One of the factors influencing this decision is the degree of function of the affected kidney. In our center we have found that renal scanning with ^{99m}technetium diethylenetriamine pentaacetic acid (^{99m}Tc DTPA), which has greater than 95% excretion by glomerular filtration, provides a simple and relatively non-invasive method for assessing the relative function on each side and for measuring the glomerular filtration rate (GFR) in children >5 years old. In children with severe hydronephrosis, ^{99m}Tc dimercaptosuccinic acid (^{99m}Tc DMSA) can be substituted to better assess relative renal function. A separate filtration rate for each kidney may be calculated from these two measurements and used to assess the patient preoperatively and to follow postoperative changes.

Despite the usefulness of these agents in special circumstances, most renal scans are done with the radiopharmaceutical ^{99m}Tc mercapoacetyltriglycine (^{99m}Tc MAG3). Dynamic images of the kidneys are taken every minute for 20 minutes after the injection. In children with hypertension or who have had a renal transplantation, we will record for the first minute after intravenous bolus injection of the radiopharmaceutical to obtain a radionuclide angiogram. Differential renal function is determined by placing regions of interest over each kidney and subtracting a local background. The reference image is the composite from 0 to 2 minutes. The net counts for each kidney (region of interest minus background) is added together to get the total functional renal mass, and a ratio of one kidney versus the other is obtained. This provides a measure of the functioning renal mass of one kidney relative to the other. Correction factors for kidney depth have been used in other centers, but we have not found these to be necessary. In a series of 13 cases in which the differential renal function measured by radionuclide techniques was compared with split creatinine clearances, the correlation coefficient was 0.96.[1] If one kidney has markedly decreased or delayed function and is not well visualized between 1 and 3 minutes, the differential renal analysis cannot be performed between the two kidneys. The differential renal function analysis is a relative measure only and an apparent decrease on one side may be due to improvement on the other side. Although the images obtained from the renal scan usually indicate which is the side that has changed, accurate diagnosis may be difficult unless a GFR is performed at the same time.

One advantage of using ^{99m}Tc DTPA is that the GFR may be measured at the same time by taking two plasma samples – one at 90 minutes and one at least 30 minutes later – and then plotting the plasma disappearance. By multiplying the percentage obtained from the differential renal functional analysis by the GFR, individual filtration rates for each kidney may be determined.[2] A variety of pure imaging techniques have been used to evaluate GFR without taking a blood sample. In children, these uptake GFR measurements have not correlated very well with blood sample methods.

The use of imaging is helpful in assessing renal function in patients with vesicoureteral reflux (VUR), ureteropelvic junction (UPJ) obstruction, ureterovesical junction obstruction, posterior urethral valves, and prune belly syndrome. It is particularly

useful in the neonate and young infant in whom a drastic improvement in renal function may be seen following surgery. Radionuclide measurement has become an integral part of the urologic assessment in pediatrics.

Congenital anomalies

Ectopic kidneys are seen well with the nuclear scan, despite bowel gas or bony structures that sometimes obscure the ectopic kidney to intravenous pyelography (IVP) and ultrasound. The diagnostic dilemma of a solitary kidney on IVP can be sorted out with the aid of a renal scan and ultrasound. These latter two modalities will distinguish renal ectopia from hypoplasia or agenesis.

The *horseshoe kidney* poses a special problem. It is often difficult to decide on the IVP if there is functioning renal tissue joining the lower poles of the kidneys because this part of the kidney overlies the spine. If one employs DMSA and takes anterior images, it is possible to detect the presence or absence of functioning tissue in the isthmus; Wilms' tumor, with which a horseshoe kidney is sometimes associated, can occasionally be identified (Figure 5.1). If horseshoe kidneys are slow to drain, one can assess obstruction using a diuretic scan.

The radionuclide renal study is frequently used to confirm the presence of *renal duplication*, suspected on IVP or ultrasound, or may even diagnose unsuspected cases. The function of each moiety can be individually assessed as well. The upper and lower parts of the duplex kidney are quantified relative to each other, as well as to the opposite kidney. This is important in deciding whether there is enough function to salvage an abnormal renal segment. Most commonly, the upper component functions less well than the lower one, because of obstruction from an ectopic ureter or ureterocele. Occasionally, however, the lower component of the duplex kidney may have less function, and in this situation one has to be suspicious of reflux nephropathy of the lower collecting system or UPJ obstruction.

Ureteropelvic junction obstruction

The child with UPJ obstruction is usually evaluated pre- and postoperatively for the degree of relative renal function, absolute renal function and rate of egress of the radioactive urine from the kidneys. Interestingly, many young children with antenatal hydronephrosis have increased renal functional mass on the side of the hydronephrosis (paradoxical hyperfunction). This has been confirmed in ^{99m}Tc DMSA studies carried out subsequent to the original diuretic washout study. In cases where an obstructive component to urine flow is suspected, a Lasix (furosemide) stress test is begun between 10 and 30 minutes after the injection of ^{99m}Tc MAG3. Intravenous Lasix (1 mg kg^{-1} to a maximum of 40 mg) is given and images recorded for 20 minutes into the computer. The clearance rate is calculated using the computer. This permits a quantitative method of determining the effect of surgery and/or postoperative complica-

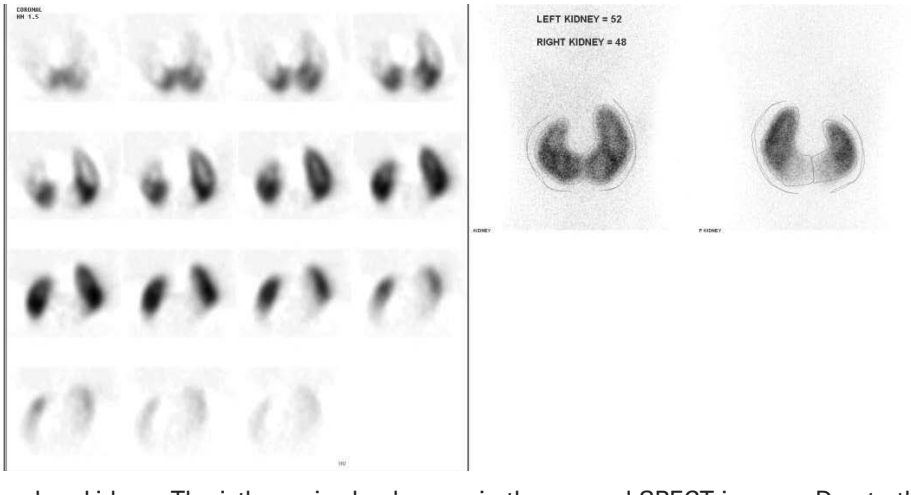

Figure 5.1 Horseshoe kidney. The isthmus is clearly seen in the coronal SPECT images. Due to the positioning of the kidneys, the relative renal function has to be calculated from the geometric mean of the anterior and posterior views.

tions on the renal drainage system. Normally the time to empty one-half of the collecting system activity ($T_{1/2}$) is less than 8–10 minutes. This value may be higher (up to 20 minutes) in grossly dilated pelves or after surgery. In cases where the $T_{1/2}$ is >10 minutes, retention at 20 minutes is calculated (counts at time '0' minus counts at 20 minutes divided by the counts at time '0') (Figure 5.2). If the patient has a $T_{1/2}$ of 20 minutes, the retention value at 20 minutes should be 50%; thus the two converge at this point. The Lasix washout study appears to reflect the state of urinary flow better than the Whitaker test in the postoperative period.

In children who have had repair of a UPJ junction obstruction or have had reimplantation of the ureters as an antireflux surgical procedure, there will be a significant delay in drainage that can persist for up to 6 months. When evaluated after that time, they usually drain normally.

Several important points have to be made regarding assessing diuretic washout curves. First, the $T_{1/2}$ is invalid when performed on normal kidneys that have already emptied their pelves. Secondly, when there is poor renal function, the kidneys cannot be evaluated as there may be poor, if any, response to the Lasix stimulation. Finally, in large hydronephrotic kidneys (pelvic volume greater than 75 ml) there will be a significant delay in emptying due to dilution, even though there may be no mechanical obstruction.

Renal transplant assessment

In children with a renal transplant, the renal scan has been used during the first 2 weeks to evaluate the effectiveness of the transplant surgery. As the art of renal transplantation has improved significantly, the need for an immediate renal evaluation is not so important. We now generally do one study in the first 48–72 hours if the urine output is normal and blood pressure and creatinine are as expected. At 2 weeks after the transplantation, we do the first GFR estimate and then on a regular basis until the child has only yearly re-evaluations. Most important observations are the glomerular filtration estimate and whether or not there is any evidence of renal infarct (Figure 5.3).

Urinary tract infection

In children with upper urinary tract infection (UTI), radionuclide techniques are the primary modalities. The direct radionuclide cystogram is the most sensitive method for detecting reflux, which is present in approximately one-third of children with upper UTI. Radionuclide cystography is a well-documented technique, with acceptable sensitivity and specificity.[3] Recently, computer-analyzed antegrade voiding cystograms have been tried and appear to be almost as accurate as the retrograde version according to some reports. This could be a preferred technique, as it is more physiologic due to the absence of bladder overfilling. However, the generally preferred method is still the catheter voiding cystogram (Figure 5.4). The monitoring of the bladder and ureters is constant throughout both filling and emptying, which is not feasible using fluoroscopy.

If the child has an upper UTI, an evaluation may be needed to determine whether or not acute pyelonephritis is present[4] with a DMSA planar or single-photon

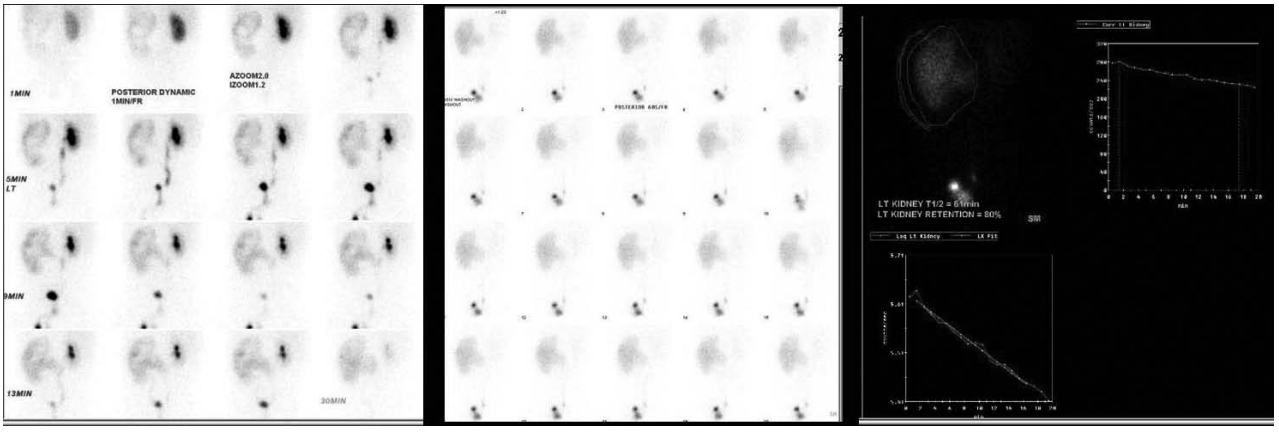

Figure 5.2 Ureteropelvic junction obstruction. The renogram images demonstrate the gross dilatation of the left renal collecting system. After Lasix (furosemide) injection there was markedly delayed drainage with a $T_{1/2}$ of 61 minutes and a 20-minute retention of 80%.

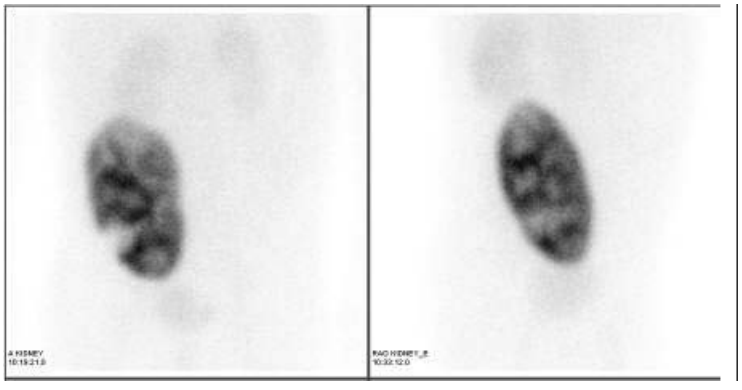

Figure 5.3 Postrenal transplant infarct. The wedged-shaped cortical defect is typical of a post-transplantation infarct.

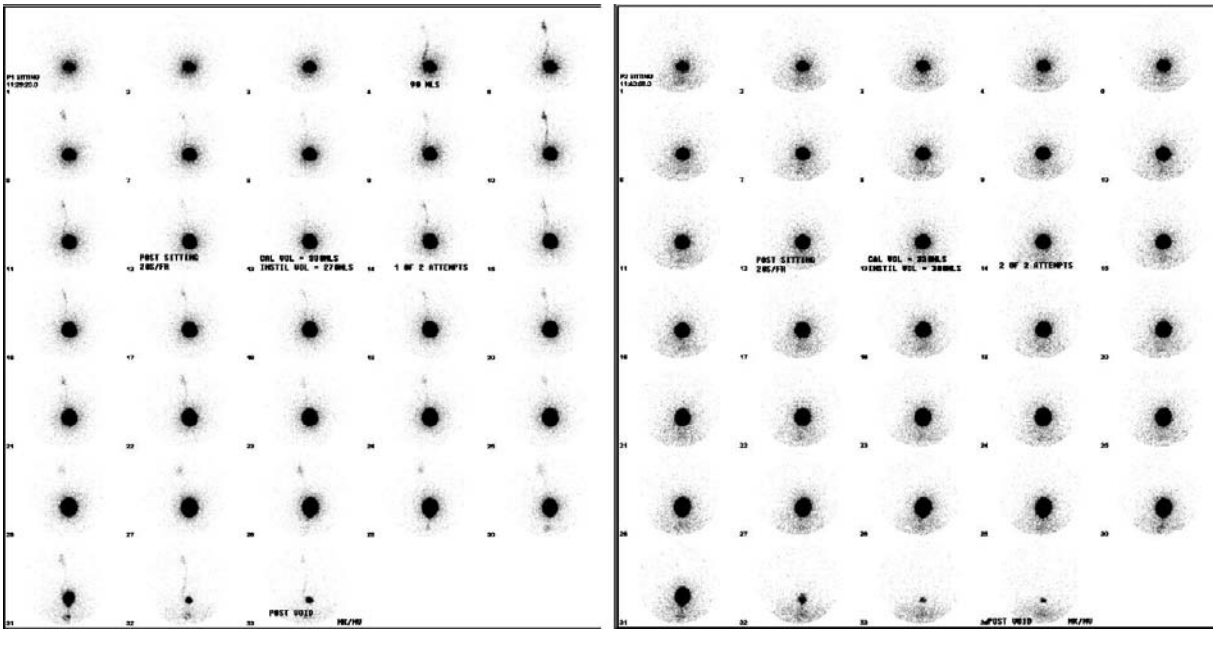

Figure 5.4 Left vesicoureteropelvic reflux. The reflux is seen to occur during filling and persist through voiding in the first attempt to fill the bladder to target capacity. In the second, no reflux occurred.

emission computed tomography (SPECT) study[4] (Figure 5.5). Recent data suggest that ultrasound should also be performed only if this a second or third UTI,[5] though most urologists have a low threshold to do a risk- and radiation-free study that can yield valuable information. Finally, a cystogram should be performed to see whether reflux is present.

Acute pyelonephritis appears as a non-segmental single or multifocal reduction in cortical accumulation of the ^{99m}Tc DMSA. In the acute phase, it is sometimes difficult to do SPECT imaging. Although it is better in defining the location of the lesions, it has only a marginal increase in sensitivity. Planar with oblique images is a satisfactory substitute. Subsequent ^{99m}Tc DMSA scans to monitor the progress of acute pyelonephritis should probably be done using SPECT imaging. In our hands and others, it has been shown that SPECT may have no increase in sensitivity in diagnosing disease, but is useful in diagnosing size and multiplicity of lesions.

A major concern after an episode of acute pyelonephritis is the development of scars. In this case, SPECT imaging appears to be the method of choice.[6] Not only is it easier to define whether scars are present or not but also location and definition are enhanced. In addition, it is much easier to determine whether splenic impression of the upper pole of the left kidney is present vs a true scar (Figure 5.6). Cortical mantle thickness is also much more readily defined.

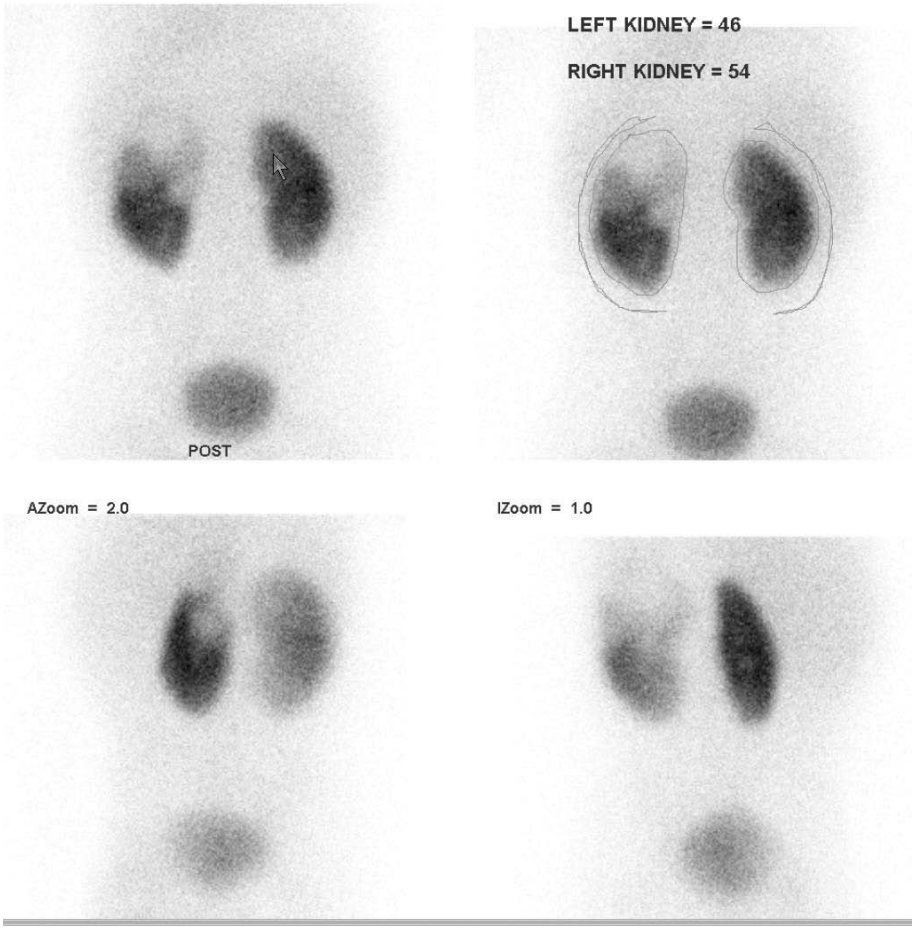

Figure 5.5 Acute pyelonephritis. A large photopenic area is seen in the upper pole of the left kidney. It is not associated with loss of cortical volume. This is the typical appearance of acute pyelonephritis.

Radionuclide cystography

Since a large number of children are seen because of UTI and VUR, isotope cystography is the preferred method for follow-up studies because of its accuracy and low radiation dose compared with conventional radiographic techniques. ^{99m}Tc pertechnetate or sulfur colloid may be instilled into the bladder via a catheter in conjunction with a saline infusion. In contrast to radiographic cystography, continuous recordings can be done during the bladder filling and voiding phases with no extra patient irradiation. Thus, chances of documenting reflux are theoretically enhanced. Conway has found good correlation with micturition cystography.[3] After the child voids, the residual counts can be used to quantify reflux and voiding volumes, since the concentration of isotope in the solution used to fill the bladder is known.

Antegrade cystography following a DTPA kidney study is an alternative method to detect VUR that avoids the problems of bladder catheterization.[7] However, it can only be carried out once the radioisotope has completely cleared from the upper tract and accumulated in the bladder. The child is then asked to void while reflux is assessed. This method compares favorably with micturating cystography and cystoscopy in some hands.

Kidney trauma

Traumatic lesions of the kidney can also be easily defined by DMSA SPECT imaging. Although ultrasound, CT, and IVPs are the common methods for evaluating trauma, sometimes the degree of functional impairment is important to know. In some institutions, SPECT imaging may be more easily and less expensively obtained. Sensitivity of SPECT ^{99m}Tc DMSA imaging for renal trauma is extremely high and is favorably compared with CT and superior to ultrasound and IVP. In fact, combined SPECT liver and spleen imaging as well as renal imaging is

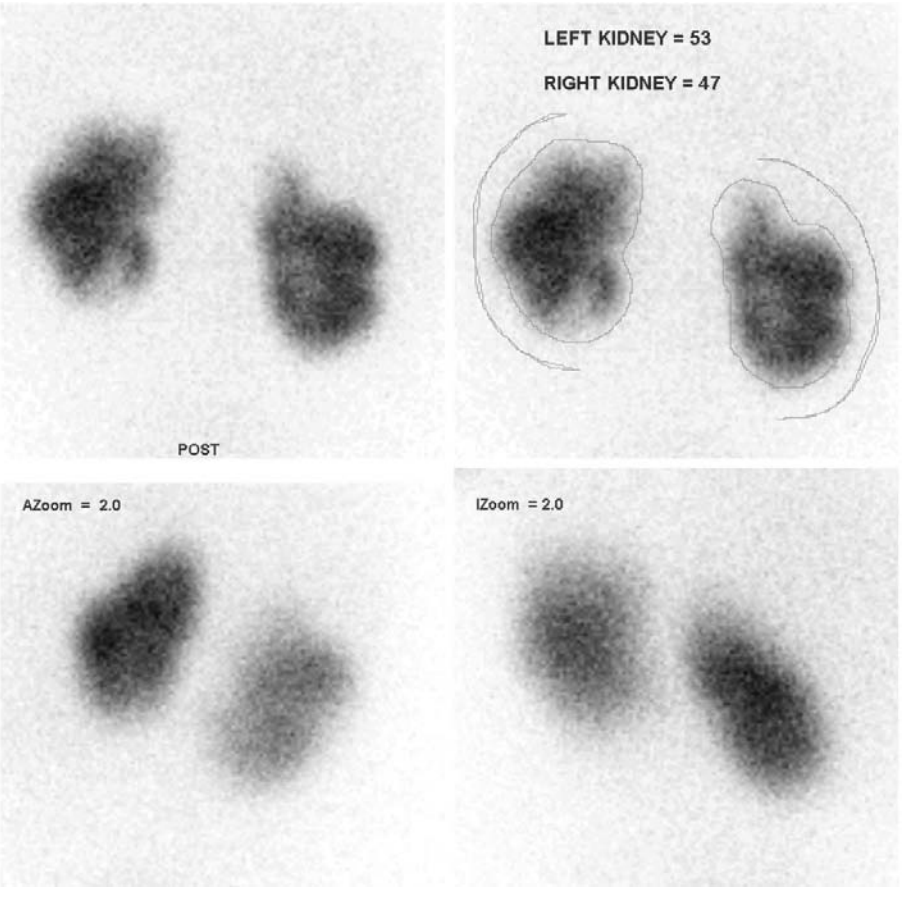

Figure 5.6 Pyelonephritic scars. Both kidneys demonstrate multiple defects with loss of cortical volume.

extremely sensitive to the overall detection of trauma of these organs. Usually, the abnormality is that of a band or section of the kidney which has depressed renal function due to fracture. Sometimes, the abnormality may be iatrogenic after interventional angiography and embolization.

Renal artery stenosis

Subsegmental or segmental renal artery stenosis is difficult to detect by the traditional nuclear medical techniques, even ^{99m}Tc DTPA imaging with captopril. In this case, we see a subsegmental or segmental reduction in ^{99m}Tc DMSA accumulation within the kidney. This is much more easily seen with SPECT than planar imaging.

Acute kidney lesions

Most of these lesions are related to hypovolemia with reduced renal perfusion. The net result in the kidney depends on the severity of the underlying clinical problem. The renal scan with its early angiogram phase has been shown to be useful in various pathologic states such as tubular necrosis, cortical necrosis, and renal vein thrombosis. The interpretation of the scan, however, must be made in light of the clinical circumstances, since other entities such as acute glomerulonephritis can look somewhat similar.

Children with acute tubular necrosis generally show good perfusion to the involved kidney. However, there is delayed excretion because radioactivity is retained within the renal parenchyma and often no activity is seen in the bladder by 30 minutes. There is no dilatation of the collecting systems to suggest hydronephrosis. In neonates the asphyxiated bladder syndrome may coexist and consists of gross bladder distention with urinary retention. Urate nephropathy of the newborn will look similar because it also causes intratubular obstruction. However, an episode of circulatory compromise is usually present to distinguish acute tubular necrosis.

Renal vein thrombosis

In renal vein thrombosis, there is poor perfusion to an enlarged kidney with poor excretion. The radio-

pharmaceutical injection should be into a suitable vein in the foot in order for the bolus to be visualized flowing up the inferior vena cava. Lack of flow implies caval thrombosis, with possible renal vein involvement. One must be wary in interpreting this, since crying, particularly in the neonate, may cause preferential flow up the paravertebral veins even with patent inferior vena cava and result in a false-positive test. It is often difficult to distinguish renal vein thrombosis from an arterial problem or intrarenal vascular problem, and this diagnosis should usually be confirmed by contrast angiography or Doppler ultrasound.

Prenatal and postnatal urologic emergencies

6

Patrick H McKenna and Fernando A Ferrer

Introduction

There are few true urologic emergencies. The object of this chapter is to cover the practical management of urgent consultations from the antenatal period through childhood. This includes a discussion of abdominal masses and intraoperative consultations. Several factors have impacted the identification and management of fetuses and children with urologically related anomalies. One of the most important factors has been the ability to identify urologic problems during fetal development. This has occurred because of increasingly accurate imaging, genetic screening, and the active participation of pediatric urologists in a multidisciplinary approach to urologic problems. As technology and genetic understanding continue to advance, the frequency with which diseases are identified in the prenatal period will continue to increase.

Antenatal period

Intervention during the antenatal period takes many forms, including medical treatment, termination of pregnancy, early induction of delivery, and surgical intervention. The incidence of prenatal surgical intervention is gradually increasing but remains rare. There are ethical, technical, and medical issues surrounding fetal surgery.[1]

Pertinent ethical issues also surround the decision to terminate a pregnancy. Discussion of the ethics of termination is beyond the scope of this chapter and is societal in nature. The pertinent ethical issues facing maternal fetal specialists and pediatric urologists that are germane to this discussion are the accuracy of the antenatal diagnosis and correct explanation of the long-term outcome of antenatally detected problems to the expecting parents. These issues are especially important in countries such as the USA where there is a time limit on the developmental date when elective termination can be performed.

Most initial screening antenatal sonograms are performed in an obstetric office. When significant abnormalities are identified, patients should be referred to centers with experience with these abnormalities to confirm the diagnosis and provide an accurate explanation of the consequences and long-term outcomes. The difficult task is providing an accurate assessment of the quality of life for patients with severe congenital abnormalities so that they can make an educated decision about intervention or pregnancy termination. Currently, severe urinary tract obstruction and congenital abnormalities, complications of intervention, and intersex disorders are the most commonly encountered antenatal problems that may involve an urgent antenatal consultation.

Urinary tract obstruction with oligohydramnios

It is estimated that only one in 30 000 pregnancies may be a candidate for antenatal intervention because of an obstructive lesion.[2–4] The most common form of intervention is the induction of early delivery after lung maturity is established. Treating the mother with corticosteroids may accelerate lung maturity in the fetus.[5] Since this is such a rare event, much of the effort of pediatric urologists has been spent in preventing unnecessary antenatal intervention. There are scant scientific data to support the efficacy of early intervention.[6–12] Published reports concerning results of intervention are mostly retrospective in nature and none has long-term follow-up.[13] In addition, the natural history of these lesions differs in the timing of presentation and their severity, even during the antenatal period, making case comparisons difficult.[14] Early severe obstruction impacts on lung development, leading to pulmonary hypoplasia.[15–17]

Urethral atresia is the most common cause of early severe hydroureteronephrosis. Posterior urethral valves (PUVs) (Figure 6.1) may present either early or late in the pregnancy with varying degrees of renal

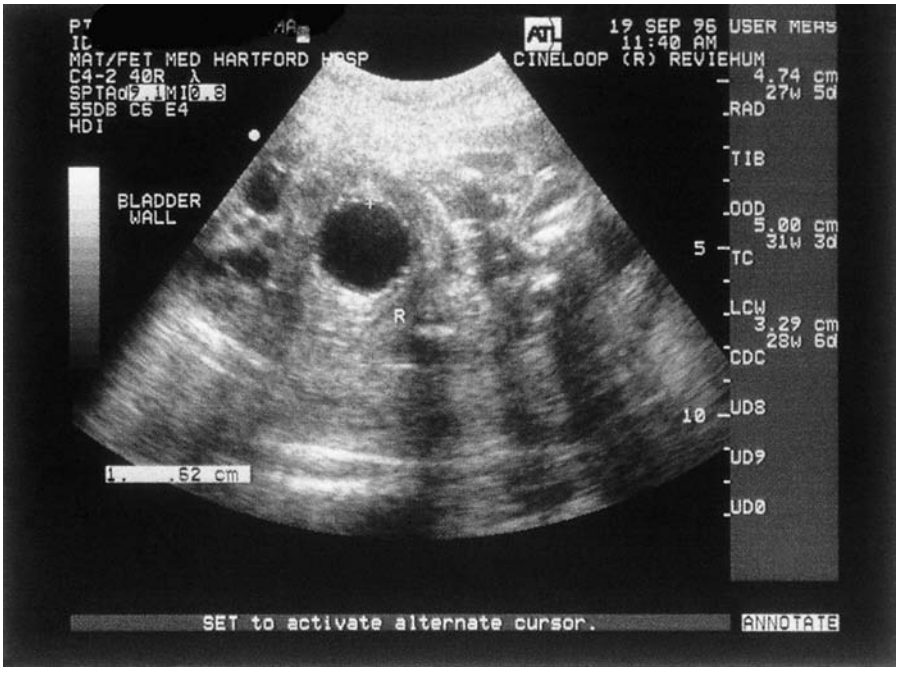

Figure 6.1 Prenatal posterior urethral valves: prenatal sonogram showing bilateral dilated renal pelvises and bladder with oligohydramnios.

injury. A ureterocele obstructing the bladder neck due to a ball-valve mechanism is another rare form of bladder neck obstruction more common in females.[18] These issues may be approached by working with maternal–fetal specialists to educate the general obstetricians on the differential diagnosis of antenatal urologic abnormalities. The flow diagram in Figure 6.2 is designed to focus the obstetrician on the importance of oligohydramnios when considering intervention. Education of obstetricians is important because ultimately they make the decisions and determine the timing of intervention. If the flow diagram is followed, only patients with oligohydramnios are even considered intervention candidates. Good prenatal sonography is accurate in making the diagnosis of PUV.[19] The correct management of these problems should involve a multidisciplinary approach since the bulk of the care resulting from the early intervention will fall to the pediatrician, nephrologist, and pediatric urologist.

In the rare instance where intervention is considered, oligohydramnios should be present, other severe congenital abnormalities should be ruled out, and evidence of recoverable renal function should be established (Figure 6.3).[20] Infusion of fluid into the amniotic space may be required to conduct an accurate sonographic survey for other severe congenital abnormalities incompatible with survival. In addition, chromosomal analysis should be obtained. Assessment of viable renal function is more difficult. It has been suggested that serial urine samples from the fetus be obtained to confirm renal function. Normal values (Table 6.1) may predict a better prognosis, as does the rate with which the bladder refills after tapping off the urine.[8,9,21–23] The reliability of these tests needs to be further documented.[24,25] In these studies, no assessment of quality of life issues in these patients was done. In cases of significant obstruction, the picture of increasing dilatation of the renal pelvis correlates with a greater likelihood of obstruction.[26] The in-utero progression of mild hydronephrosis is usually less than 15%.[27] No prospective studies have been performed comparing intervention to observation. Since these severe abnormalities are so rare,

Table 6.1 Fetal urine electrolytes suggesting good renal function (bladder aspirates)

	Value
Sodium	<100 mEq/L
Chloride	<90 mEq/L
Osmolarity	<210 mOsm/L

single-center experiences are always few. A multicenter registry was attempted in the past but only a small number of patients was entered and long-term follow-up was not obtained.[28] The single-center review of 14 patients with follow-up greater than 2 years revealed that five patients required renal transplantation, three had renal insufficiency, and six had normal renal function.[11] Ultimately, multicenter studies will be required to answer many of the questions concerning appropriateness of intervention. A survey of practicing pediatric urologists confirmed that few recommend antenatal intervention. When it is considered, the strict criteria outlined above should be followed.[29] Ideally, intervention should take place before any renal injury occurs. This approach can only take place if future studies can accurately identify obstruction very early in the antenatal period, which is currently rarely accomplished.

Complications of antenatal intervention

Intervention in the antenatal period can take various forms, from medical treatment to surgical intervention. The consequences of antenatal medical treatment for congenital adrenal hyperplasia (CAH) exemplify some of the ethical and practical problems with prenatal treatment of the fetus with medication. The risks to the fetus escalate the more invasive the form of antenatal intervention. Amniocentesis during the second trimester has become almost a routine procedure. When it is done with ultrasound guidance there is a 1% incidence of spontaneous abortion.[30,31] Fetal hemorrhage, cord laceration, direct fetal injury, uterine injury, and chorioamnionitis have been reported after amniocentesis. But, when amniocentesis is performed using specific guidelines by experienced teams, these risks are minimized.[32,33] Chorionic villus sampling historically had a fetal loss rate of approximately 3.5% and infection rates of 0.25–0.5%.[34,35] Recent data suggest that chorionic villus sampling may be safer than early amniocentesis.[36]

More invasive intervention, including percutaneous procedures and open surgery, are associated with more significant problems. The main abnormalities currently considered for intervention include fetal urinary tract obstruction, myelomeningocele, fetal diaphragmatic hernia, fetal cystic adenomatoid malformation, and fetal sacrococcygeal teratoma.[37,38] Even the most invasive procedures have minimal maternal risks or effect on future maternal fertility.[39]

The most common complication of hysterotomy for fetal intervention is subsequent uterine contractions with premature delivery.[40,41] Development of better tocolytic agents and other methods to prevent uterine contraction is crucial to successful prenatal surgery. The increased use of percutaneous laparoscopic surgery may decrease the problems of uncontrolled uterine contractions. However, laparoscopy is associated with an increased risk of percutaneous access wounds. Risks include injury to other fetal organs and to the abdominal wall.[42–49] Once intervention is anticipated, the pediatric team, including the maternal–fetal obstetrician, pediatric urologist, and neonatologist, should be available because complications such as uncontrolled uterine contraction or serious fetal injury may require immediate delivery, infant resuscitation, or surgical intervention.[4]

Classic bladder exstrophy

The antenatal identification of exstrophy is relatively straightforward. A combination of characteristics can be identified on a screening sonogram. The five most commonly identified findings are (1) no visualization of the bladder; (2) a lower abdominal bulge; (3) small penis and anteriorly placed scrotum; (4) a low-set umbilicus; and (5) abnormal widening of the iliac crests.[50] Omphaloceles are usually associated with a midline defect at the umbilical insertion, gastroschisis most frequently consists of a small, right-sided paraumbilical defect, and large lateral defects usually occur in the limb–body wall complex. In addition, specific organ evisceration and other associated abnormalities assist in the differential diagnosis.[51,52] More recently, the use of fetal MRI in the antenatal diagnosis and accurate determination of fetal gender has been reported by Hsieh[53] (Figure 6.4).

The challenge in the antenatal identification of these abnormalities is to provide counseling to the parents at the time when the abnormalities are identified.[54] The best approach is to involve a physician familiar with the long-term outcome of patients with these complex reconstructive problems. Initial work on the psychosocial and physical outcome of patients treated with various surgical approaches has begun but the outcome is known in a small number of patients.[55–57] Although some broad generalizations can be made, more outcomes data will be required to confirm early results. In the initial reviews, concerns centered primarily on worries about sexual function and sexual disfigurement, whereas education, family life, and employment appear to be essentially normal. The males were concerned about the appearance of

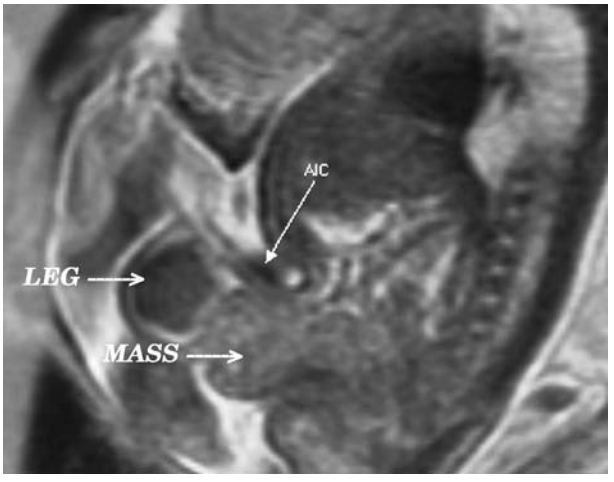

Figure 6.4 Determination of fetal gender using MRI.

their external genitalia, even though their sexual function was preserved. The female patients were less concerned about disfigurement and had normal sexual function, sexuality, and fertility. A complete understanding of the underlying anatomical abnormalities and the approach in the surgical reconstruction are requirements for the appropriate counseling of these patients.

Neural tube defects

Although not primarily a urologic abnormality, neural tube defects result in significant urinary tract morbidity. The accurate diagnosis of neural tube defects during the antenatal period can result from a combination of routine screening of maternal serum α-fetoprotein and targeted sonography.[58] Neuropathic bladder effects have been detected before birth.[59] The decreasing incidence of neural tube defects in the newborn period is due to the increased use of folic acid by childbearing women[60,61] and the increase in termination of affected fetuses during pregnancy.[62] The Public Health Service of the USA currently recommends that all women capable of childbearing consume 0.4 mg folic acid per day to decrease the risk of neural tube defects and anencephaly. Recently, it has been determined that the neurologic abnormalities associated with neural tube defects may result primarily from prolonged exposure of the neural tube to amniotic fluid. Intrauterine repair of spina bifida in fetuses with a ventricular size of <14 mm, fetuses who had surgery at or before 25 weeks, and fetuses with defects that were located at or below L4 were less likely to require postnatal ventriculoperitoneal shunting.[38] The fetal intervention may not improve the ultimate bladder function and these patients should be managed urologically similar to spina bifida patients that did not undergo fetal surgery.[63] The level of the defect, timing of repair, and type of repair all affect the outcome. Long-term follow-up of antenatally treated patients is not available and urologic participation in the postnatal evaluation and follow-up will be crucial to determine the possible benefits of the antenatal surgical approach.

Solid masses

The antenatal identification of a solid mass seldom requires early intervention but often generates an urgent consultation. The commonly detected antenatal masses include:

- adrenal hemorrhage
- neuroblastoma
- congenital mesoblastic nephroma
- Wilms' tumor
- pulmonary sequestration
- teratoma
- sacrococcygeal teratoma
- hepatic lesions
- rhabdomyosarcoma.

Since hydronephrotic and cystic lesions are easily distinguished by sonography the list is predominantly made up of rare but reported lesions. The recommendation should be to evaluate these patients thoroughly after delivery.

Intersex disorders

The identification of intersex disorders in the antenatal period is the result of better screening techniques and advances in the understanding of the inheritance of these diseases. Unlike the postnatal period, where the discovery of ambiguous genitalia is the initiating factor, amniocentesis, chorionic villus sampling, and better sonographic techniques allow early identification of many intersex disorders in the antenatal period.[64–68] The prenatal identification of these problems results in the need to provide adequate prenatal counseling.[69] Identifying CAH before birth provides the opportunity to treat the fetus in the hope of preventing androgen effects on fetal development, though presumptive early therapy is most effective in those known to have a familial risk.[70–76]

Most intersex disorders other than CAH are identified inadvertently.[77] In some cases this is the result of an amniocentesis because of a simple parental request to know the sex of the fetus. In other cases, there can be an issue of other known inheritable diseases such as determining the likelihood of an X-linked disorder (e.g. hemophilia). Knowing the sex may be helpful in confirming the cause of a structural disorder (e.g. PUV) that does not occur in girls. In cases with a family history of CAH genetic sampling can identify the inherited genetic disorder. The identification of an intersex disorder may also result from routine screening of an older mother. In situations where the genetic sex is known, but the genital screening by ultrasound does not appear to match the genotype, clinicians should consider the possibility of an intersex disorder. In the case of a 46,XY karyotype with female-appearing genitalia, the differential diagnosis should include gonadal dysgenesis or androgen insensitivity. In severely androgenized females with CAH, a 46,XX karyotype may be associated with ultrasound findings suggesting male genitalia. Table 6.2 lists the chromosomal analyses and possible intersex disorders.

The ability to identify and medically treat a disease in the antenatal period will probably become the norm in the future; however, the consequences of prenatal treatment need to be completely understood before it is openly embraced. Accuracy of the antenatal diagnosis and the effect of the medical treatment on other aspects of the fetus' development must be understood before treatment becomes routine. There is no better example of this controversy than the current debate over prenatal treatment of CAH.[78–80] Prenatal treatment of CAH needs to start before 6 weeks' gestation to completely prevent androgenic effects. Chorionic villus sampling to obtain fetal DNA cannot be done until 10–12 weeks' gestation.

The most common cause of CAH is 21-hydroxylase deficiency. This deficiency results in the inability to synthesize cortisol. The pituitary and hypothalamus overstimulate the adrenal gland, causing the overproduction of androstenedione. The androstenedione is further metabolized, predominantly to testosterone and dihydrotestosterone, resulting in the prenatal virilization of the female fetus. Early treatment with dexamethasone can prevent or minimize severe genital abnormalities in some patients.[73,81–83] The risk of having an infant with CAH for a mother with classic 21-hydroxylase deficiency is 1 in 8. The complications of prenatal treatment to the fetus, maternal risks, and long-term effects to the child are incompletely understood. Since antenatal treatment with dexamethasone needs to begin at 6 weeks' gestation, seven fetuses are treated unnecessarily to affect the external genital development of one fetus. This has significant ethical implications. The fetal metabolism of dexamethasone is not understood, and the doses recommended for treatment are greater than required to suppress the adrenal in the adult.[78] The effect on unaffected fetuses is not completely known. Despite these concerns, the possibility of preventing androgen imprinting of the brain in the affected female fetuses justifies a controlled long-term study.

Postnatal period

In the past, urologic problems identified at birth were primarily obvious congenital abnormalities such as

Table 6.2 Chromosomal analyses and possible intersex disorder

46,XX	Female pseudohermaphrodite (usually CAH) Male pseudohermaphrodite (i.e. SRY positive) True hermaphrodite Gonadal dysgenesis
46,XY	Male pseudohermaphrodite True hermaphrodite
46,XX/XY	True hermaphrodite
45,X, 45,X/46,XX, 45,X/46,XY, others	Gonadal dysgenesis Mixed gonadal dysgenesis Male pseudohermaphrodite True hermaphrodite

exstrophy. Now, the majority of urologic problems seen by urologists in the immediate postnatal period are identified by prenatal sonography and magnetic resonance imaging (MRI). In the evaluation and treatment of these problems physicians need to consider the unique aspects of bonding between the infant and the parents.[84,85] Bonding can be affected by separation of the infant from the parents and by severely disfiguring congenital anomalies.[86,87] These considerations should impact the treatment of infants with and without obvious congenital abnormalities. The support needs go beyond helping the family to come to grips with the congenital anomaly, and should include dealing with parental fears concerning job loss, financial difficulties, and effects on other family members.[86] One should encourage early discharge of infants who can be adequately managed as outpatients. When prolonged hospitalization is required, parental rooming-in with the infant is encouraged. A psychiatrist and staff educated on bonding issues should be actively involved in patient and parental management.[88–90]

Congenital anomalies noted at birth

Anorectal malformations

Anorectal malformations (imperforate anus) are congenital lesions of the cloaca (Figure 6.5). It is important for urologists to be familiar with these malformations because they are often associated with urologic abnormalities. There is also a high incidence of other congenital abnormalities associated with such malformations. There are multiple classification systems but none has gained wide acceptance. From a urologic perspective the simple distinction of 'high', 'intermediate', or 'low' anorectal lesions is probably sufficient: low lesions are those that occur inferior to the levator muscles, high lesions occur above the levator muscles, and intermediate ones in between (Figure 6.6).[91] From a clinical point of view most intermediate lesions are treated as high lesions. The surgical correction of these malformations is most often by a technique popularized by de Vries and Pena[92] using the posterior sagittal approach. Associated urologic abnormalities occur in up to 20% of patients with low lesions and up to 60% of those with high lesions.[93,94] The most common findings are vesicoureteral reflux (VUR), neuropathic bladder, renal agenesis, renal dysplasia, and cryptorchidism. It is not surprising that there is a high incidence of neuropathic bladder because of the likely

association of vertebral abnormalities with anorectal malformations, especially with high lesions. Neuropathic bladder may occur in as many as 50% of patients.[93] The most common anatomic abnormality in patients with vertebral abnormalities is a tethered cord. Only recently has this association been identified and linked to the high incidence of neuropathic bladders and dysfunctional pelvic floors.[95] Patients with anorectal malformations should be studied urodynamically if they have high lesions and/or spinal abnormalities.

Exstrophy

Classic bladder exstrophy still most commonly presents at the time of birth despite the known specific antenatal sonographic findings[50] (Figure 6.7). The typical infant is male and is otherwise healthy. An exstrophic bladder, abdominal wall defect, epispadias, pelvic diastasis, VUR after bladder closure, and bilateral inguinal hernias characterize the anomaly. Initially, much time is spent with the family explaining the disease and planning the bladder closure. Patients should be managed by a urologist with exstrophy closure experience. The initial treatment is to protect the exposed bladder mucosa. If a plastic umbilical clamp was placed in the delivery suite it should be removed and replaced with a suture. If possible, nothing should come into contact with the bladder mucosa. A modified humidifier tent can be placed over the bladder, but for transport a cellophane non-adherent dressing may be utilized.[96]

The traditional methods of reconstruction used a staged strategy,[97,98] the first stage involving bladder and abdominal wall closure with pelvic osteotomy in most cases (Figure 6.8).[97,98] The epispadias is reconstructed in the next stage, and finally the incontinence and reflux. Several centers have advocated combining the first stages into one operation soon after birth (see Chapter 55). Initial reports are encouraging, but few patients have been treated in this way and there is little long-term follow-up.[96,99] Combined closure and

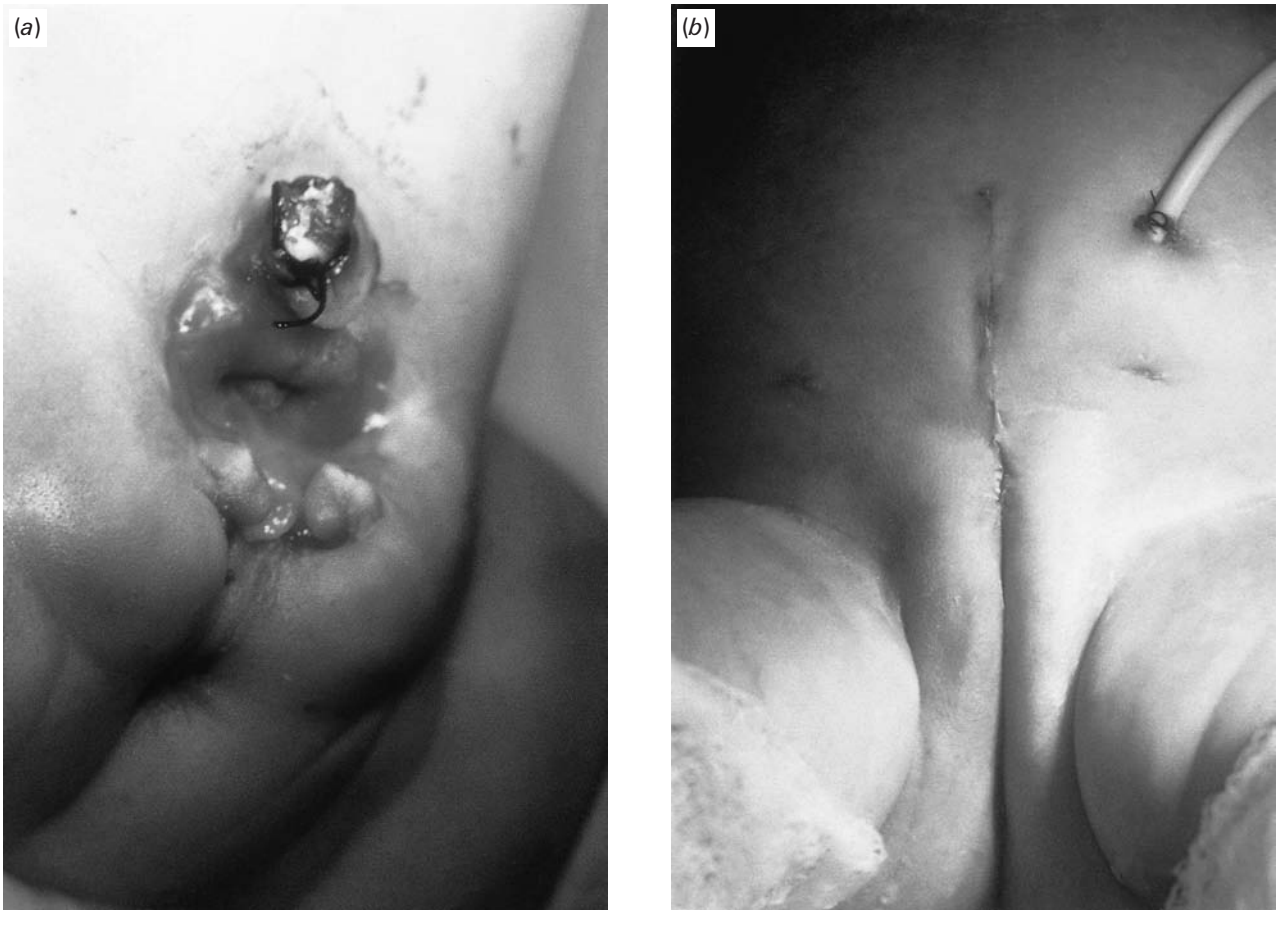

Figure 6.7 (*a*) Newborn female exstrophy patient; (*b*) 4 weeks after initial closure.

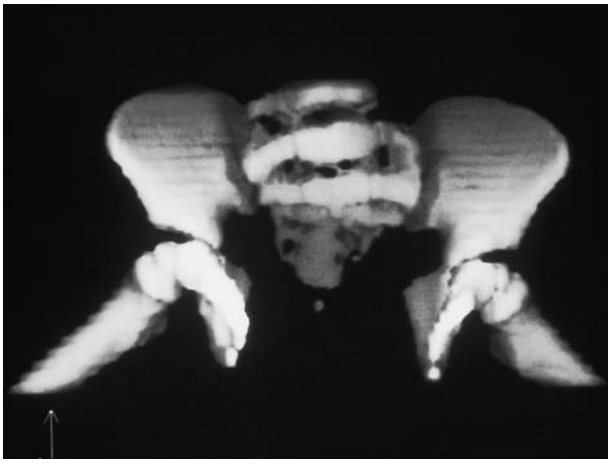

Figure 6.8 Three-dimensional CT reconstruction of a 5-year-old male with uncorrected classic bladder exstrophy showing a wide separation of the pubic bones and flattening of the ilial bones.

epispadias repair can lead to its own unique set of complications, including loss of the hemi-glans or glans, and hypospadias,[100] although either of these complications can potentially be seen after more traditional reconstruction.

Exstrophy reconstruction has led to a greater understanding of sphincter and pelvic floor anatomy and function. Patients have improved pelvic floor reconstruction and better continence rates after osteotomy.[101–104] This is likely to be due to better approximation of the pelvic floor muscle. In addition, there is a close relationship between bladder size and continence. In situations where capacity is inadequate, bladder augmentation, bladder neck closure, and a catheterizable stoma may provide the best alternative.[98]

Prune belly syndrome

Deficient abdominal wall musculature, cryptorchism, and urinary tract dilatation characterize this syndrome. Other names include triad syndrome, Eagle–Barrett syndrome, and abdominal muscular deficiency syndrome. The spectrum of this disease is wide. It ranges from in-utero demise, renal dysplasia and subsequent renal failure, to normal renal function. The pathogenesis is not completely understood.[105] The presumptive prenatal diagnosis has been made as early as 12 weeks' gestation.[106] In the most severe forms, identified antenatally, there is complete urethral obstruction. In the antenatal period these patients are often confused with patients who have severe PUV and may be inadvertently combined in retrospective reviews.[8] One terminated fetus had urethral atresia with histologically normal kidneys, which may mean that there is a role for intervention in cases identified very early.[107] The postnatal evaluation should include sonography, voiding cystourethrography (VCUG), and renal scan when indicated, though VCUG can be avoided to reduce the risk of early urinary tract infection. Although predominantly affecting males, a female variety has been described.[108] Initially, medical treatment (i.e. antibacterial prophylaxis and perhaps circumcision in babies with reflux) and close surveillance are indicated in all but the most severe cases where vesicostomy or upper tract diversion may be needed.[109–111] In the long term, a combination of continuous antibacterial prophylaxis, well-planned surgery, and close surveillance is the best means to ensure an optimal outcome.[110,112–115] Severity of the congenital renal dysplasia, nadir creatinine >0.7 mg/dl, recurrent pyelonephritis, and renal obstruction all correlate with eventual development of renal failure.[113,115] Treatment of the undescended testes should be similar to that recommended for other patients with abdominal testes. Early orchidopexy should be accomplished and may be facilitated by laparoscopy.[116] No prune belly patient has been known to father a child; however, early testis biopsy has identified spermatogonia, so fertility is possible using in-vitro fertilization.[117,118] The histologic findings of significantly reduced spermatogonia and marked Leydig cell hyperplasia suggest that the pathology of the testis in prune belly syndrome is secondary to more than just its abdominal location. Testis tumors have developed in these patients.[119–121]

Myelodysplasia

In the past myelodysplasia was the most common cause of neurogenic bladder dysfunction in children. Its incidence has been steadily decreasing because of early detection in the antenatal period resulting in termination of the pregnancy, and maternal folic acid treatment which markedly decreases the likelihood of developing spinal defects.[47,122–124] There is a slight increase in the incidence of myelodysplasia if other family members also have the condition.[125]

Open myelomeningoceles (Figure 6.9) are readily identifiable at birth. The level of the lesion does not correlate with the neurologic defect because some nerve roots may be left intact. An Arnold–Chiari

Figure 6.9 Newborn with myelomeningocele.

malformation can affect the brainstem and pontine micturition center. It is this malformation that is most likely to be prevented by fetal surgery. Tethering of the spinal cord and different growth rates in the distorted vertebral bodies can affect the final neurologic deficit.[126] Likewise, immediately after birth and during infancy and early childhood, a changing pattern is often seen in the urodynamics of these patients.[127–129] It is impossible to make broad generalizations, but in children with high thoracic lesions, patients may have an intact sacral reflex arc. Those with lesions at S1 and below can have normal bladder function but upper or lower motor lesions involving the bladder and/or pelvic floor are also seen. Complete urologic evaluation after closure of the defects including renal sonography, VCUG, and full urodynamic assessment is advisable because sphincter dyssynergia and uninhibited bladder contractions may be predictive of future upper tract deterioration.[127,130–133] Clear evidence exists that starting prophylactic treatment in situations where there is high risk for deterioration (uninhibited bladder contraction and elevated storage pressure in association with sphincter dyssynergy) is beneficial in decreasing the likelihood of upper tract and bladder deterioration.[134–136] Management usually involves initiation of clean intermittent catheterization (CIC) and anticholinergic medication. The dynamic nature of this disease requires routine surveillance throughout the patient's life, but particularly during periods of rapid linear growth, when spinal cord tethering may occur.[136,137]

Lipomeningocele

This abnormality is difficult to identify on physical examination. It is important to have a high level of suspicion and to examine the lower spine carefully because the vast majority of children with lipomeningocele have an identifiable superficial or cutaneous lesion. The neurologic changes occur because of an intradural lipoma. This lesion results in a broad spectrum of disease and presentation.[138] Typically, during early childhood, there are few outward physical abnormalities and only with complete urodynamic assessment is the effect on the bladder identified.[139] The most common urodynamic findings are consistent with an upper motor neuron lesion. Sphincter dyssynergy is less often identified in this group. In older children where the diagnosis has been delayed there are often neurologic changes in the lower extremities.[140] The bladder changes in the older group are mixed between detrusor hyperreflexia and detrusor areflexia. The best methods to identify and characterize these lesions are MRI and complete urodynamic assessment.[141]

Sacral agenesis

This lesion is even more difficult to identify on physical examination, and often the patient presents at an older age with failure to become continent.[142,143] Loss of the lower vertebral bodies can be easily seen on a lateral lower plain film of the spine or on an MRI study. White and Klauber[144] suggested that palpation of the coccyx could identify absent vertebral bodies, but radiographic confirmation is the best method. These patients have a stable neurologic lesion that does not progress with growth. However, the results of urodynamic studies are variable.[145] Patients may have no sign of denervation or hyperreflexia, areflexia, intact sphincter function, or sphincter dyssynergy, and some have absent control over the sphincter.[146] A high level of suspicion and complete urodynamics help to guide treatment.[142] Specific intervention is based on the identified findings.[143]

Scrotal masses

Palpation of a scrotal mass commonly results in an urgent consultation. When it is of an acute nature with pain, testicular torsion is the most important diagnosis to consider. This represents a true surgical emergency. It is best managed by early exploration, detorsion, and, when the testis is salvageable, fixation. If the testis is not salvageable it should be removed. In either instance, the contralateral testis should also be sutured to the scrotal wall.

The history should focus on the age of the patient, whether there is associated pain, and whether there is a history of trauma. The onset and severity of pain may be helpful in the differential diagnosis of torsion versus epididymitis. The physical examination should focus on identifying the location of the mass in relation to the testis. The orientation of the testis should be evaluated. Normally, the epididymis is posterior and lateral to the testis. Careful palpation will identify torsion of appendices such as the appendix testis, both anterior and superior appendices of the epididymis, and the hydatid of Morgagni that is located in the posterior inferior epididymal testicular ridge.[147] In non-acute masses, sonography is important to confirm the location and architecture of the mass. Possible scrotal masses are:

- hydrocele
- incarcerated hernia
- torsion of the testis
- appendage torsion
- testis tumor
- epididymitis
- epididymal cyst
- epididymal tumor
- paratesticular tumor
- varicocele
- Henoch–Schönlein purpura
- idiopathic edema
- cavernous hemangioma
- funiculitis
- lesions that result from a patent process vaginalis.

Neonatal scrotal masses

History plays very little role in the diagnosis in neonates.[148] The specific differential diagnosis of such masses includes:

- hydrocele
- incarcerated hernia
- torsion
- lesion secondary to patent processus vaginalis
- meconium
- testis tumors
- trauma.

The initial evaluation of these infants involves a complete physical examination. Perinatally, firm enlarged scrotal masses may be hydroceles but the diagnosis of bilateral torsion should be considered.[149] Positive transillumination can often aid the differential diagnosis. Occasionally a plain abdominal film may be helpful in identifying bowel gas in the scrotal mass that would indicate an inguinal hernia with bowel in the scrotum, or calcification suggesting old meconium. If the mass is associated with thickened cord structures or if it can be reduced, a hernia is also likely. Ultrasound examination can differentiate solid and cystic masses. Doppler ultrasound can often confirm blood flow, but can be misleading in the small child.

Prenatal testis torsion is also referred to as neonatal torsion, extravaginal, intrauterine torsion, antenatal torsion, perinatal torsion, and newborn torsion. There is controversy over the mechanism of the torsion, risk of bilaterality, and need for and timing of contralateral fixation.[150–152] When torsion occurs before delivery it has been thought to occur extravaginally, involving the entire spermatic cord and its tunics. Some physicians believe that this process can occur very early in the pregnancy and that it is responsible for most instances of testicular agenesis.[153–155] It is impossible to determine whether all cases are extravaginal and at least some probably represent intravaginal torsion, as seen in older boys. When torsion occurs prior to delivery the presentation is one of a non-tender, discolored, solid scrotal mass. Doppler ultrasound is generally accurate in confirming the diagnosis.[156–160] The torsion is most often unilateral but over 30 bilateral cases have been reported.[158,161,162] A strong case has been made for early exploration, with orchiectomy when the testis is necrotic, and contralateral fixation, as many examples of subsequent contralateral torsion have now been reported.[163–165] The arguments in favor of early exploration include: relative safety of anesthesia in the neonatal period; possibility of testicular salvage (10%), particularly the hormonal function; ability to fix the contralateral testis to prevent asynchronous torsion in the future; and to confirm the diagnosis.

Lesions that result from a patent processus vaginalis include meconium mass, hemoscrotum from intra-abdominal hemorrhage, and tumor seeding

from renal or adrenal tumors.[166–170] Spontaneous rupture of the bowel can occur during fetal development, resulting in meconium peritonitis. If the processus vaginalis is still open at that time the meconium can fall into the scrotum and present as a solid mass at birth. Stippled calcification is usually present. Likewise, other anomalies such as adrenal hematomas, neuroblastoma, and Wilms' tumor can also seed the scrotum through a patent canal and should be considered in the differential diagnosis of neonatal scrotal masses. All of these suggest the utility of abdominal ultrasonography at discovery of the scrotal mass.

Testis tumors are also seen in the neonatal period but are rare (Table 6.3).[171] Yolk sac tumors, teratomas, gonadal stromal tumors and juvenile granulosa cell tumors are the most common. Early radical surgical removal is the recommended treatment for those with malignant potential, with chemotherapy in selected cases.

Pediatric scrotal masses

In older patients history plays a greater role in the differential diagnosis. Torsion has a bimodal distribution: in the perinatal period and at or before puberty.[172] When there is sudden onset of severe pain associated with nausea and scrotal swelling, torsion should be suspected and represents a true surgical emergency. On examination of the scrotum there is no spermatic cord swelling in acute torsion. The cremasteric reflex is generally absent, though this can be an inconsistent finding, and the testis is tense to palpation and rides high in the scrotum.[173] The epididymis will either not be palpable or is palpable in an abnormal location. Urinalysis is usually normal. Torsion is usually confirmed by surgical exploration; however, in centers with rapid access to color Doppler ultrasound the diagnosis can be confirmed before intervention.[174–176] In most cases history and physical examination are sufficient for diagnosis, and radiologic evaluation is only performed in those in whom the diagnosis is unlikely. Detorsion can take place prior to exploration by manually untwisting the involved testis. The most common direction of torsion is from lateral to medial (when viewing the scrotum from the patient's feet), so detorsion manually should be from medial to lateral (again viewing the scrotum from the patient's feet). If detorsion is unsuccessful, attempts in the other direction can be tried. Once the direction is determined, the testis will spin rapidly and complete resolution of pain confirms detorsion. The testis should still be fixed in place by suture to prevent recurrent torsion. Torsion in the pediatric period is usually intravaginal and secondary to a bell-clapper deformity. Torsion should be relieved within 4 hours to be certain of testis viability, but detorsion after 12 hours has resulted in viable testis tissue in some cases; by 24 hours there is almost uniform eventual atrophy if the testis is left in place.[177–179] Cases where there has been testicular salvage after longer periods probably represent intermittent or incomplete torsion. Spermatogonia appear to be more sensitive to ischemia then the Sertoli and Leydig cells.[180] Since the bell-clapper deformity can affect both testes, the contralateral testis should be fixed at the time that the involved testis is explored. In a typical pediatric emergency room, 16% of the patients who present with an acute scrotum will have testis torsion, 46% will have torsion of an appendix of the testis, 35% will be identified as epididymitis, and the remainder are other lesions.[181] It appears that treatment with human chorionic gonadotropin (hCG) may occasionally induce torsion in the undescended testes[182] (Figure 6.10).

Epididymitis should also be considered in boys with acute scrotal pain. It usually presents as scrotal swelling with gradually increasing pain. Physical examination isolates pain to the epididymis. The cremasteric reflex is often intact.[183] Elevation of the testis may improve the pain (Prehn's sign). When pyuria is present, this supports the diagnosis, but in children it is often not present. Sonography shows a hyperemic swollen epididymis.[184] The causes of epididymitis include trauma, infection, or reflux of sterile urine. Since the cause may not be identified at diagnosis, treatment should include scrotal elevation, bed rest, antibiotics if the urinalysis is positive, and an anti-inflammatory medication. In sexually active teenagers possible *Chlamydia trachomatis* infection should be treated, and in non-sexually active children treatment

Table 6.3 Neonatal testicular tumors

Tumor	Frequency (%)
Yolk sac	27
Gonadal stromal tumors	27
Juvenile granulosa cell tumors	27
Gonadal blastoma	9
Teratoma	5
Harmartoma	5

should be directed toward *Escherichia coli*. In boys with proven bacterial epididymitis there is a high probability of an anatomic abnormality. After treatment, full examination of the upper and lower urinary tract should be accomplished with ultrasound and a VCUG.[181]

Pediatric scrotal tumors are rare and include primary testis lesions, paratesticular tumors, and metastatic or lymphatic tumors:[185]

- mature teratoma
- teratocarcinoma
- yolk sac tumor
- paratesticular rhabdomyosarcoma
- gonadal stromal tumors
- granulosa cell tumors
- cavernous hemangioma
- gonadoblastoma
- metastatic tumors.

Ultrasound is helpful in locating the origin of these lesions but the diagnosis is made by surgical exploration through a groin incision. It is inadvisable to explore tumors through a scrotal incision because such intervention can theoretically change the direction of lymphatic spread of the tumor, though there is little evidence that this actually happens. Once the tumor is removed, pathologic evaluation determines the diagnosis. A combination of surgery, chemotherapy, and radiation has resulted in a high cure rate.[107,171] Benign testis lesions in prepubertal children can be removed by partial orchiectomy, avoiding loss of the entire testis.

Another scrotal lesion that may present as a scrotal mass is a varicocele. It is usually left sided and disappears when the patient lies flat. Intervention is indicated if it is associated with ipsilateral testicular growth failure. Other intrascrotal lesions are extremely rare, usually benign, and identified by history, physical examination, ultrasound, and biopsy[185–187] (Figure 6.11). The more common superficial lesions such as funiculitis and idiopathic edema should be considered when the scrotal contents are normal (Figure 6.12).

Intersex disorders

A consultation for ambiguous genitalia is one of the urgent problems that a urologist must face. The initial approach to managing intersex patients is to identify and treat possible life-threatening abnormalities.[188–190] In most instances sexual assignment is straightforward, and, where it is not, consideration should be given to delaying the decision to intervene surgically until the infant is older[189,191] (see Chapter 58).

CAH is the most common cause of ambiguous genitalia at birth. It is the only form of intersex that can be life threatening. The possible enzyme deficiencies include 21-hydroxylase, 11β-hydroxylase, 20,22-desmolase, and 3β-hydroxysteroid dehydrogenase. In 21-hydroxylase deficiency, lack of mineralocorticoid and glucocorticoid cause an electrolyte imbalance resulting in elevated serum potassium and low sodium that lead to dehydration or potentially lethal cardiac arrhythmias. The excess androstenedione that

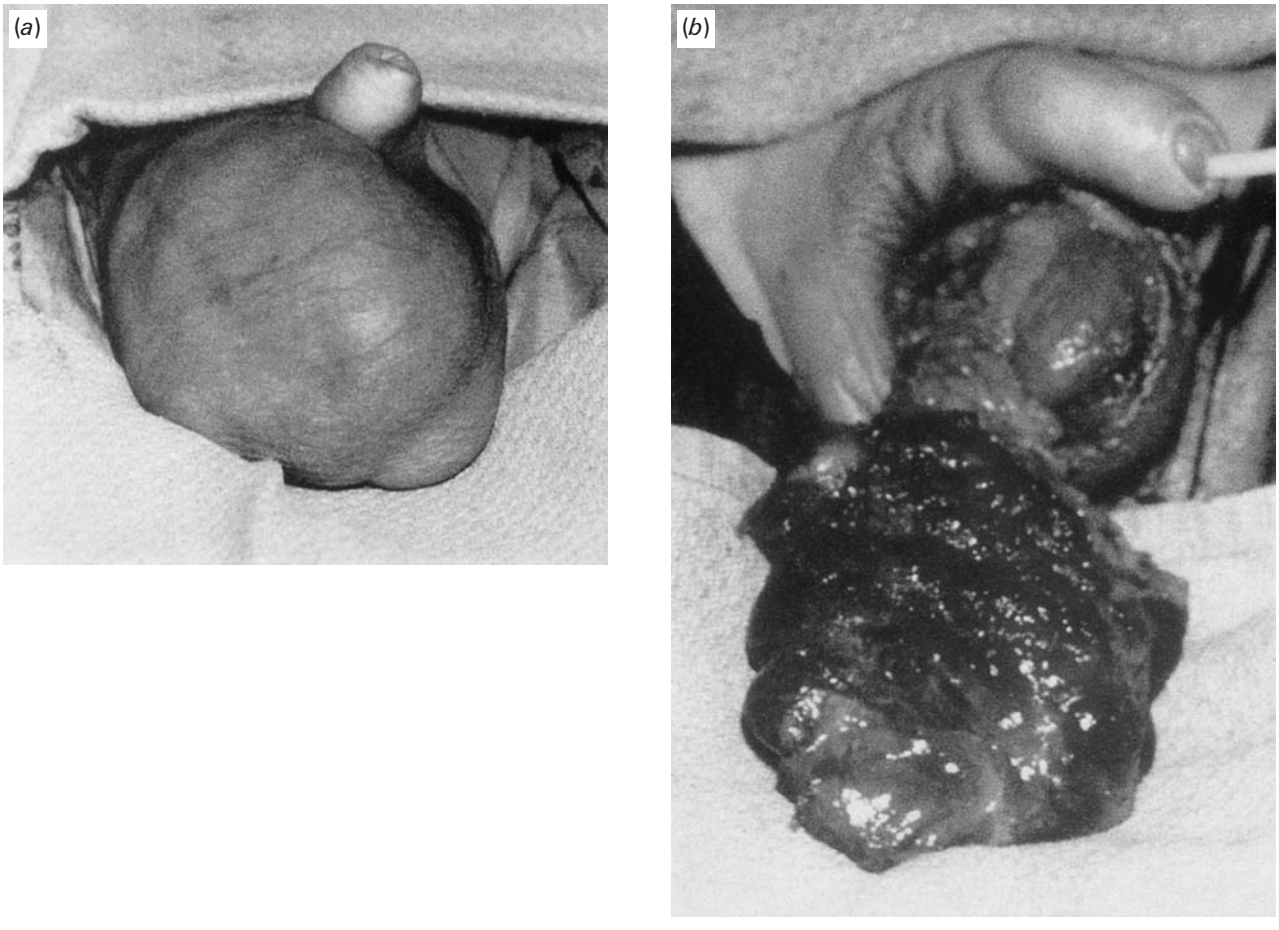

Figure 6.11 (*a*) Preoperative picture of scrotal cavernous hemangioma; (*b*) intraoperative picture of a cavernous hemangioma.

Figure 6.12 Idiopathic edema.

builds up behind the enzymatic block metabolizes to testosterone and dihydrotestosterone, causing virilization of the female infant (Figure 6.13). Physical examination and screening laboratory studies facilitate the differential diagnosis relatively rapidly. The infant will have varying degrees of masculinization, from hypertrophy of the clitoris and mild labioscrotal development to a normal-appearing male phallus and scrotum. The gonads are symmetrical and typically non-palpable. The Barr body is positive, and pelvic sonography identifies a uterus and ovaries. Müllerian inhibiting substance is undetectable, and the chromosome evaluation is 46,XX. Serum studies should include electrolytes, glucose, gonadotropin, dihydrotestosterone, testosterone, and adrenal steroid levels. Initial treatment involves glucocorticoid and mineralocorticoid replacement. It is strongly recommended that these patients be reared as female because of the chromosomal sex and potential fertility, but in the most virilized form questions have arisen as to the best sex of rearing.[192,193]

Although CAH is the most common intersex disorder, it is important to have a diagnostic plan for evaluating all intersex patients. The differential diagnosis method used by the authors is based on history, chromosome determination, serum tests, screening radiological studies, and pathology (Figure 6.14).

The initial history should focus on pedigree and

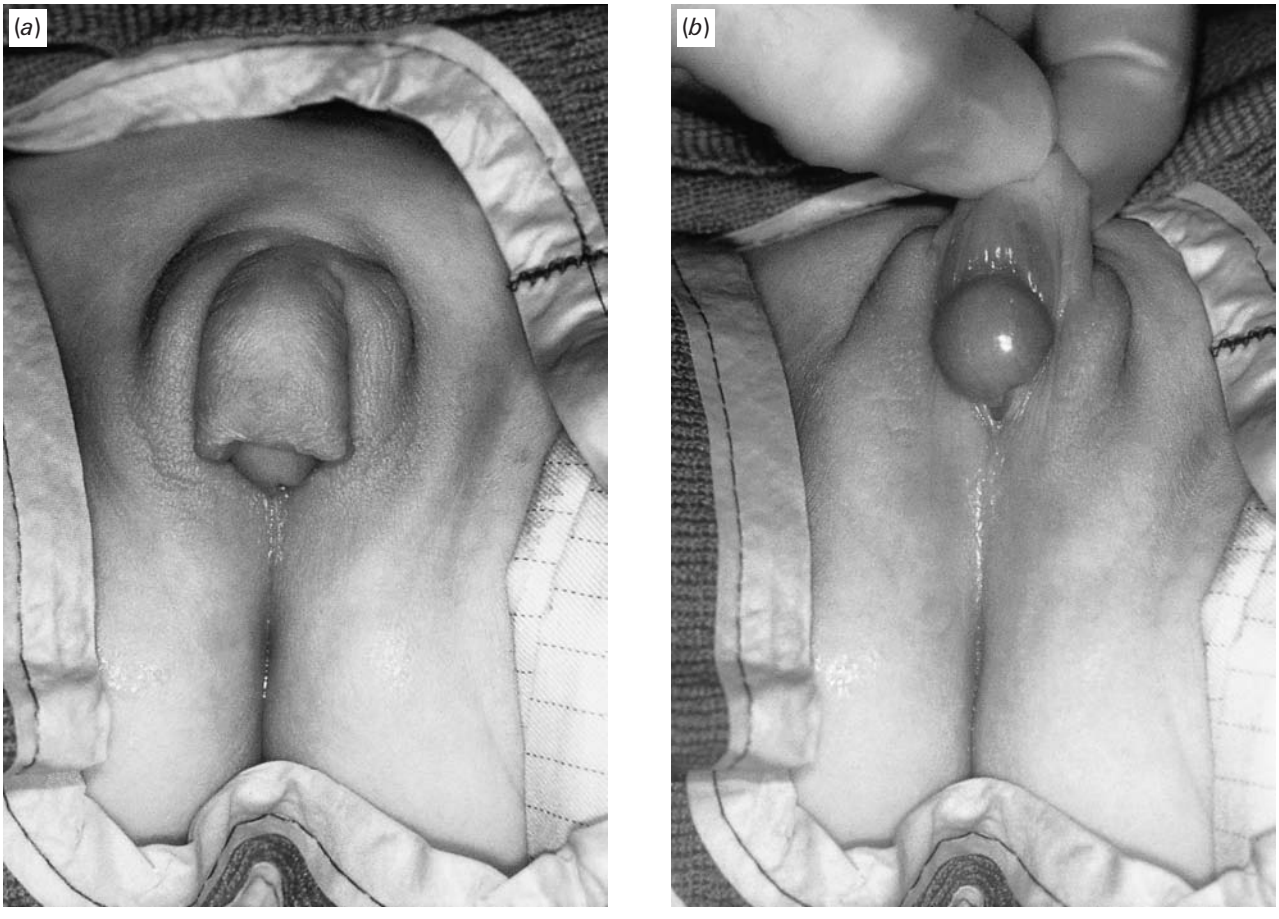

Figure 6.13 Severely androgenized patient with congenital adrenal hyperplasia.

drug ingestion history. Physical examination should concentrate on palpating the gonads. If no gonads can be palpated in the masculinized baby, one should consider female pseudohermaphroditism (FPH), gonadal dysgenesis (GD), male pseudohermaphroditism (MPH), and true hermaphroditism (TH). When only one gonad is palpable one should consider mixed gonadal dysgenesis (MGD), TH and MPH. When both gonads are palpated one should consider MPH and rarely TH. The next step involves targeted laboratory and radiologic screening. Initial evaluation should include measuring serum electrolytes, 17-hydroxyprogesterone, testosterone and dihydrotestosterone (DHT) levels, and determining karyotype. Screening sonography and genitography in appropriate situations are helpful in the evaluation.

When 17-hydroxyprogesterone is elevated, the karyotype is 46,XX, and a uterus is identified by ultrasound, one is dealing with CAH. Checking the 11-deoxycortisol levels can differentiate between 21α-hydroxylase and 11β-hydroxylase deficiency. If the 17-hydroxyprogesterone levels are normal and a uterus and ovaries are identified in a child with a 46,XX karyotype, a maternal virilizing syndrome should be considered.

In the remainder of cases, 17-hydroxyprogesterone will not be elevated. A combination of ultrasound findings and laparoscopy with or without biopsy is often required to make a definitive diagnosis. If two testes are identified, an hCG stimulation test should be performed. Serum testosterone, DHT, dehydroepiandrosterone (DHEA) and androstenedione should be measured before and after stimulation. This will identify MPH (46,XY, 46,XX, 45,X/46,XY). There are a number of causes of MPH, including testicular failure, dysgenetic testes, steroid deficiency secondary to male CAH, complete androgen insensitivity syndrome, and 5α-reductase deficiency.

When laparoscopy and biopsy identify a streak gonad, one should consider gonadal dysgenesis, which is pure gonadal dysgenesis with both gonads represented as streaks (45,X, 45,X/46,XX, 45,X/46,XY), or mixed gonadal dysgenesis with a streak gonad and testis (45,X/46,XY, 46,XY). In cases with both a testis and ovary or ovotestes, one should consider true hermaphroditism (46,XX, 46,XX/XY, 46,XY).

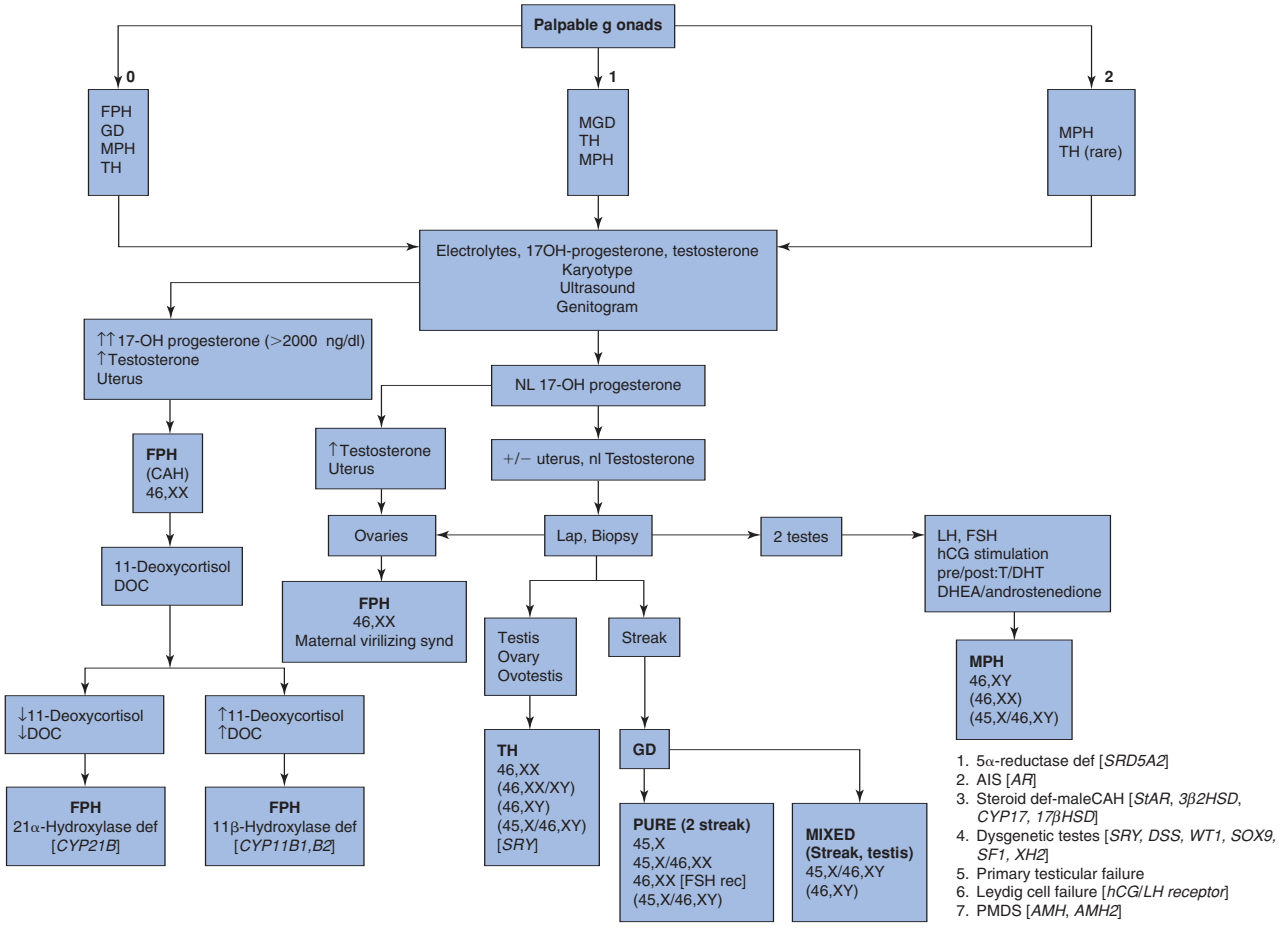

Figure 6.14 Differential diagnosis of intersex disorders. (Adapted from flow diagram presented to the Society for Fetal Urology in 1999 by Thomas Kolon MD.) (FPH = female pseudohermaphroditism; GD = gonadal dysgenesis; MPH = male pseudohermaphroditism; TH = true hermaphroditism; MGD = mixed gonadal dysgenesis; CAH = congenital adrenal hyperplasia; AIS = androgen insensitivity syndrome; PMDS = persistent Müllerian duct syndrome; genes are in italics (uncommon karyotypes in square brackets).

Posterior urethral valves and lower urinary tract abnormalities

This cause of lower urinary tract obstruction is now commonly diagnosed presumptively in the antenatal period. Previously, infants presented with failure to thrive, an abdominal mass, or urosepsis.[194] Common antenatal ultrasound findings include a distended thick-walled bladder, bilateral hydronephrosis, and oligohydramnios in some cases.[19,194,195] Although the outcomes of patients diagnosed antenatally may be worse than those diagnosed postnatally, this is indicative of a greater severity of disease and should not be taken to mean that antenatal diagnoses will not improve outcome in these patients.[196]

There is significant variability in the treatment of infants with PUV. Appropriate treatment is usually determined based on the overall medical condition of the infant, including renal function, hydrational status, presence of infection and lung maturity, as well as caliber of the urethra. In general, some basic tenets are applicable to most cases. Catheter drainage of the bladder will allow decompression of the urinary tract and prophylactic antibiotics should be initiated at birth. Initial measures of renal function are reflective of the mother's kidney function; therefore, catheter drainage should be maintained until the nadir creatinine is reached.[197–200] If the creatinine falls below 1 mg/dl, valve ablation with pediatric endoscopic equipment should be performed, after which careful monitoring of renal function, bladder function, and reflux should be continued while the child remains on antibiotic prophylaxis.[201,202]

Infants whose renal function does not substantially improve pose a much more difficult management problem. In these patients minimizing intrarenal pres-

sure may have a positive effect on renal function. These patients may have either low or high urinary diversion.[197,198,203,204] Whereas upper tract diversion was commonly used in the past, vesicostomy is usually the initial step to decompress these kidneys. Upper tract diversion does not appear to have an adverse effect on bladder function.[205] Consideration to upper tract diversion may be given in severe cases in order to minimize intrapelvic pressures and in those with urinary infection, as this optimizes renal drainage. However, little evidence exists that upper tract diversion really helps, unless infection has been present, and it complicates subsequent reconstruction. Long-term outcome in these patients depends essentially on the degree of renal damage and on bladder function.[196,206] Older children may require anticholinergics and/or bladder augmentation for the 'valve bladder' with high storage pressures. Reimplantation to correct reflux may be necessary: The worst cases come to dialysis and eventual transplantation.

An ectopic ureterocele can present as an obstructing lesion at the bladder neck. This condition occurs with a female prevalence of approximately 3–4:1.[207–209] Cases in which the ureterocele creates a ball-valve obstructive mechanism have been reported and these have been detected antenatally.[209] Bilateral ureteroceles have also been diagnosed by ultrasound prior to birth. In general, these patients are managed initially by transurethral incision[210–214] (Figure 6.15). Once stabilized, they undergo final management, which may include treatment of reflux, excision of the ureterocele, and in some cases upper pole nephrectomy and ureterectomy.[207] As in all cases of lower urinary tract obstruction, treatment of long-term bladder dysfunction may be required. Infection is another indication for ureterocele incision.

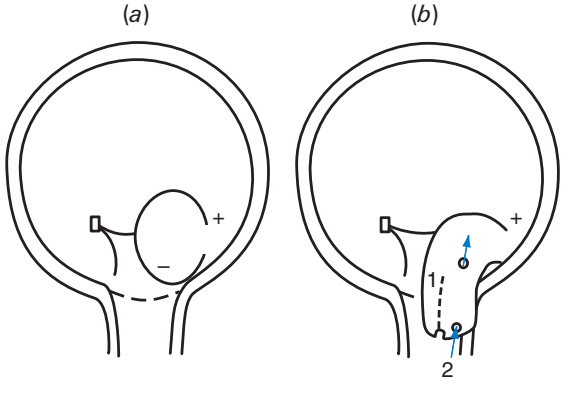

Figure 6.15 Technique for incision of ureteroceles: (*a*) incision for an intravesical ureterocele; (*b*) techniques for an ectopic ureterocele: (1) incising proximally, (2) puncturing urethal and intravesical segments separately. (From Blyth et al,[210] with permission.)

VUR can be the cause of the upper tract dilatation in as many as 35% of children with antenatal hydronephrosis.[67] Recent reviews suggest that this is less likely in African–Americans and more common in males than females[215,216] but all should be screened. Children with dilated upper tracts should have a VCUG to rule out reflux prior to treatment for other urinary tract abnormalities.[217]

Circumcision injuries

Circumcision is the most common surgical procedure performed in the USA, with approximately 600 000 to 700 000 operations performed annually.[218] A recent report suggests that circumcision rates are actually increasing in the USA. It was estimated in the period 1988–1991 ~48% of newborns underwent neonatal circumcision versus ~61% in the period 1997–2000.[219] Absolute indications for neonatal circumcisions are few.[220,221] In neonates with prenatally detected hydronephrosis, especially when reflux is identified, circumcision may be recommended because it decreases the likelihood of an early urinary tract infection (UTI).[67,222,223] Reports demonstrating a marked change in the periurethral and glanular bacterial flora in boys after circumcision support this practice.[224] Indications for circumcision in older children include persistent phimosis, paraphimosis, and recurrent balanitis. A viable alternative to circumcision in infants and older children is the use of steroid cream.[225,226] This is typically accomplished by applying 0.05% betamethasone cream to the prepuce twice daily for 4 weeks. Success rates of roughly 70–90% have been reported. Paraphimosis is best treated by pressure on the edemetous preputial skin and reduction of the paraphimotic skin. If the glans cannot be replaced, a dorsal slit incision in the phimotic skin allows reduction. Circumcision in infants with known bleeding disorders, hypospadias, and congenital anomalies of the penis, buried penis, or prematurity should be delayed to a later date.[227]

Complications of circumcisions are infrequent, occurring in 0.2–3%.[228]

1 Early acute complications:
   - bleeding
   - infection
   - laceration
   - amputation, usually partial
   - urinary retention

- skin loss
- necrosis, sometimes due to overuse of cautery.

2 Non-acute complications:
- skin excess
- skin asymmetry
- skin bridges
- skin chordee
- epidermal inclusion cysts
- concealed (buried) penis
- phimosis
- meatal stenosis
- urethrocutaneous fistula
- circumcision despite hypospadias, removing skin needed for repair
- plastibell specific
- lymphedema.

The majority of circumcision complications are minor.[229–236] The incidence of complications is probably higher than reported in the urologic literature since many are treated without referral and some do not present until the patient is much older. Complications are best prevented by strict attention to the details of the procedure, which include sterile technique, hemostasis, protection of the glans, and removing the appropriate amount of inner and outer preputial skin.[237–239] Certain anatomic variations may predispose to complications during neonatal circumcision. Caruso et al suggested that a prominent fat pad, penoscrotal webbing, or prematurity are associated with a higher incidence of circumcision complications.[240] When complications occur, immediate attention and treatment is the best management.[241–245] Bleeding is best managed by pressure, placing an absorbable stitch, or with electrocautery, though electrocautery should never be used with a metallic clamp device in place because of the risk of penile necrosis. Most of the cases that require immediate repair involve laceration or amputation of a portion of the glans (Figure 6.16). Commonly, these result from a circumcision done using a Mogen clamp placed at an angle incorporating the frenulum which draws up the glans into the clamp.[243] If the amputated portion of the glans can be retrieved it can be reapproximated with absorbable sutures. When amputation occurs, the amputated portion of the glans should be wrapped sterilely and kept cool on ice, but not submerged in saline. In most instances it can be reattached utilizing long-lasting absorbable sutures (i.e. PDS).[242,243,245,246] Amputation of a portion of the penis involving the urethra should also be repaired by immediate reconstruction. Results are best if reapproximation occurs within hours of the injury; however, successful reapproximation after delays of up to 18 hours have been reported.[247] Most urethral injuries should have a staged reconstruction, although fistulae can be closed immediately if recognized.[244]

Penile skin loss as a result of circumcision can usually be managed conservatively by application of antibiotic impregnated gauze. Ingrowth of skin usually results in a good cosmetic appearance. Skin grafting is rarely necessary. Sometimes an apparently normal penis with a complete circumferential prepuce is found to have a hypospadiac meatus when the skin

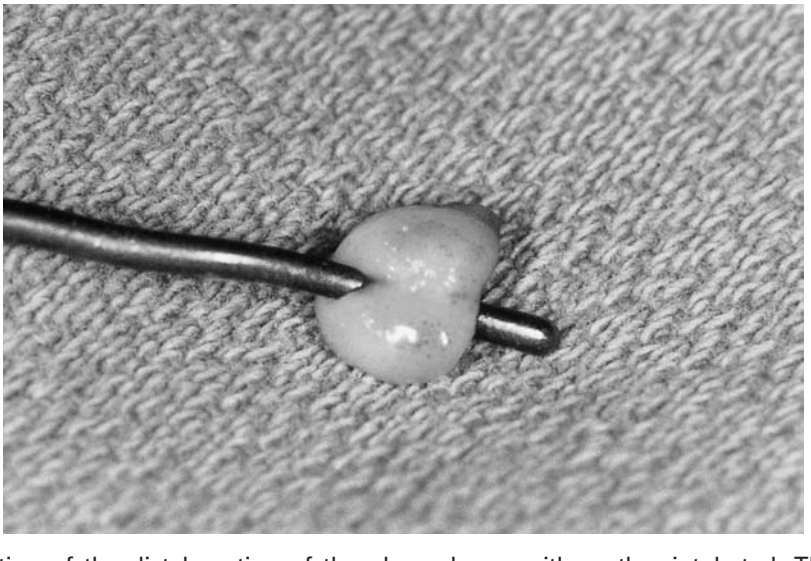

Figure 6.16 Amputation of the distal portion of the glans shown with urethra intubated. This was successfully reattached.

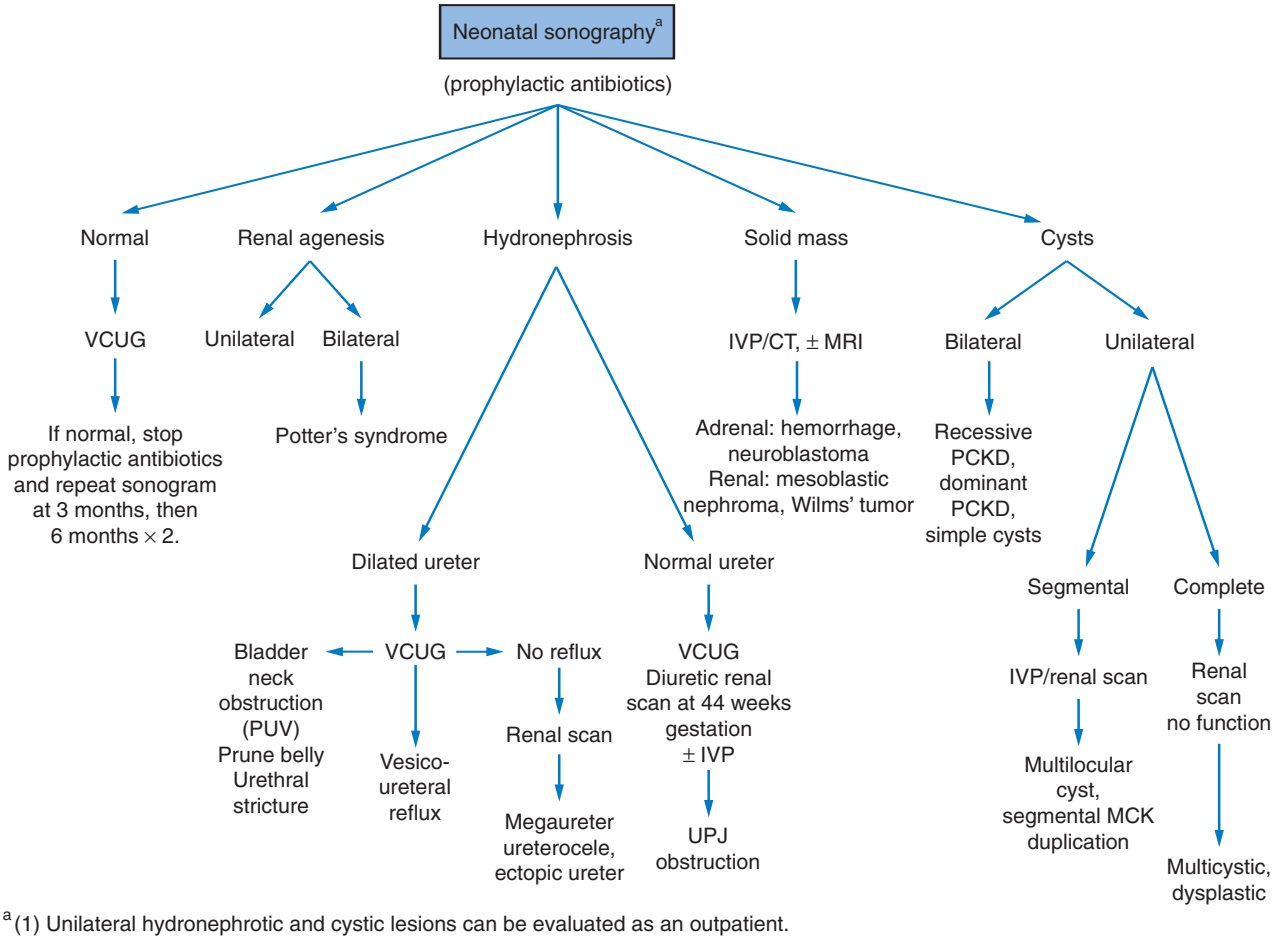
is incised or retracted. This rare form of hypospadias is called megameatus with intact prepuce. The circumcision should be discontinued and any remaining skin left attached for possible later use in hypospadias repair. Plastibell circumcisions have their own specific complications, including a higher incidence of delayed wound infections and retained plastic cuff. Concealed or buried penis can result when the glans penis recedes below the circumcision scar and the scar then contracts[248] due to insufficient removal of inner prepuce.

Recently, much emphasis has been placed on the appropriate form of analgesia for circumcision. The best method of providing a penile block is with a ring block using lidocaine.[249–253] Single injection on the dorsum is the next best approach. EMLA cream requires a prolonged exposure to provide deep superficial analgesia[254] and often results in moderate preputial edema; consequently, it has not been the authors' method of choice.[255] A recent double-blinded study has suggested that EMLA cream can provide equivalent analgesia to a bupivacaine dorsal penile block without complications, suggesting that this is a reasonable alternative.[256]

Abdominal masses in the infant

The neonate presenting with an abdominal mass is of particular importance to the pediatric urologist because the majority of such lesions arise in the retroperitoneum in general and the kidney specifically.[257,258] Traditionally, they presented with a palpable mass. Although some still present this way, masses are far more likely to be detected by prenatal sonography. At the time of presentation to the urologist most have already been categorized as solid, cystic, or hydronephrotic. The urologist must be familiar with the masses that originate from the genitourinary tract as well as the following broad spectrum of other potential etiologies:



1 Hydronephrotic and cystic lesions:
   - hydronephrosis
   - multicystic dysplastic kidney
   - cystic nephroma
   - autosomal recessive polycystic kidney disease
   - autosomal dominant polycystic kidney disease.
2 Midline-pelvic cystic lesions:
   - hydrometrocolpos
   - ovarian cyst
   - distended bladder
   - urinary ascites.
3 Solid lesions:
   - neuroblastoma
   - congenital mesoblastic nephroma
   - Wilms' tumor
   - rhabdoid tumor
   - clear cell sarcoma
   - angiomyolipoma
   - ossifying tumor of the kidney
   - renal vein thrombosis
   - renal artery thrombosis
   - adrenal hemorrhage.
4 Non-genitourinary lesions:
   - pulmonary sequestration
   - hepatic lesions
   - gastrointestinal lesions
   - germ cell tumors
   - sarcoma
   - sacrococcygeal teratoma.

Figure 6.17 provides a flow diagram that outlines the general framework used to evaluate the lesions identified antenatally. The evaluation of an infant with a mass often becomes a continuation of the evaluation that began prenatally. It is important to note that neonates with masses represent a diagnostic emergency for both parent and referring physician, but rarely do they require emergency surgery and prenatal intervention is almost never indicated.

Hydronephrotic lesions

Ureteropelvic junction (UPJ) obstruction causing hydronephrosis remains one of the most common causes of an abdominal mass in the neonate.[259] The diagnosis is almost always made by prenatal ultrasound.[260] Significant hydronephrosis has an incidence of approximately 1:600 infants; however, hydronephrosis causing an abdominal mass is much less common.[261] Barring the development of oligohydramnios or anhydramnios, most fetuses are observed until term delivery. UPJ obstruction is usually unilateral but can be bilateral in up to 20–40% of cases.[262]

Postnatal management includes prophylactic antibiotics and postnatal sonography. The authors typically wait 48 hours after birth to perform sonography to minimize the incidence of false-negative studies, although the data suggest that this traditional delay is unnecessary.[263] Clearly in the face of a neonate with a mass no delay is warranted. If hydronephrosis is detected and no ureter is visualized, the presumed diagnosis of UPJ is made. A VCUG will exclude the possibility of ipsilateral or contralateral reflux. This test should be performed before any intervention is considered. To establish the diagnosis,

[a] (1) Unilateral hydronephrotic and cystic lesions can be evaluated as an outpatient.
(2) Bilateral lesions should be evaluated prior to discharge.
(3) Masses should be evaluated prior to discharge.

Figure 6.17 Postnatal flow diagram. (VCUG = voiding cystourethrography; IVP = intravenous pyelogram; CT = computed tomography; MRI = magnetic resonance imaging; PCKD = polycystic kidney disease; PUV = posterior urethal valves; UPJ = ureteropelvic obstruction.)

a well-tempered renogram is performed. When performing Lasix (furosemide) renograms it is important to optimize the study by following an accepted protocol and ensuring that the infant is well hydrated.[264,265] Prophylactic antibiotics are discontinued when reflux and obstruction are excluded.

In cases where it is believed that the obstructed kidney may have minimal function, proceeding with evaluation and treatment earlier is often indicated because the neonatal kidney has significant ability to regain function. When presentation involves an abdominal mass from massive hydronephrosis, evaluation of viable renal parenchyma is difficult. In these cases a period of percutaneous drainage followed by nuclear scintigraphy to evaluate function may reveal a salvageable renal unit. A biopsy at the time of surgical correction has the best predictive value with regard to future renal function (Figure 6.18).[266] If no function is present on the renal scan the diagnosis of multicystic dysplastic kidney (MCDK) must be considered.

Treatment of the UPJ depends on the degree of obstruction and whether the lesion is unilateral or bilateral.[267] Clearly, children with significant bilateral obstruction require early intervention. Since surgical repair of UPJ in infants does not have a higher complication rate than in larger children, age does not affect the decision to intervene surgically.[268]

Renal cystic lesions

Increasingly, cystic mass lesions in the neonatal period are detected antenatally by sonography. In evaluating these lesions it is useful to divide them into

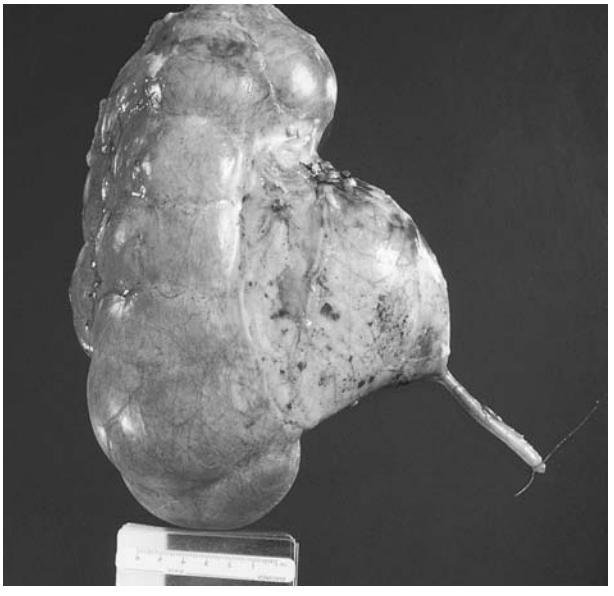


Figure 6.18 End-stage ureteropelvic junction obstruction showing how the dilated calices can mimic cystic structures.

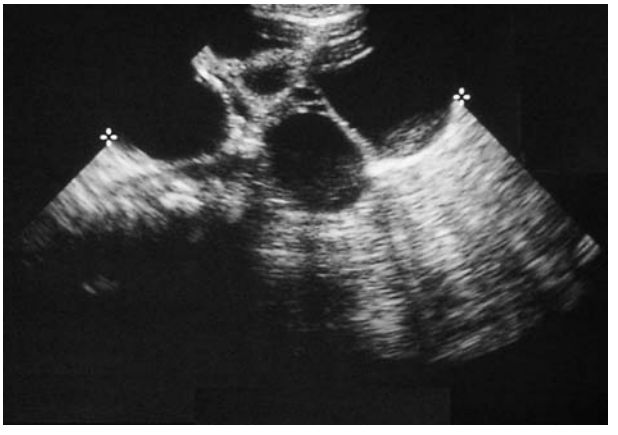

Figure 6.19 Sonogram of multicystic dysplastic kidney. (From Anthony Balcom, Milwaukee, WI, with permission.)

unilateral and bilateral categories. This allows a natural division of diagnostic possibilities.[269] Most lesions are detected antenatally but do not require intervention or further evaluation until after birth.

Unilateral lesions

MCDK is the second most common cause of an abdominal mass in infants.[270] Usually the mass is unilateral and may be palpable as a multilobular 'cluster of grapes' that transilluminates. These lesions may be quite large and can impede normal feeding because of compression of the stomach; alternatively, they may impinge on the diaphragm and affect respiration. Importantly, this lesion has a high incidence of associated contralateral renal abnormalities. Contralateral lesions are seen in upwards of 25% of these children.[271,272] The two most common kidney lesions are UPJ obstruction and contralateral VUR. Miller et al[273] recently reported an incidence of contralateral VUR of 26.4%. The majority (89%) of the VUR was low grade (I or II). The majority of the cases underwent spontaneous resolution. While US evaluation of the contralateral kidney should be performed, the need for a VCUG in cases where the contralateral kidney is normal by sonography is controversial.

Diagnosis of MCDK is usually made postnatally with a sonogram, which shows a multiloculated mass with little parenchyma (Figure 6.19). The cysts are generally non-connected. When the cysts appear to be connected, the diagnosis of severe UPJ obstruction should be entertained. Although there are reports of familial lesion, most are sporadic and familial screening in the absence of a significant familial history is not warranted.[274] The diagnosis is confirmed with a dimercaptosuccinic acid (DMSA) scan that demonstrates no function of the affected side. Contralateral imaging with sonography to rule out obstruction or bilateral MCDK is mandatory. Ureteral atresia is associated with a higher incidence of contralateral abnormalities than is renal pelvic atresia.[275]

Whereas previously nephrectomy was commonly performed, today serial sonography is the standard. Multicystic kidneys typically regress.[276,277] To date no reliable predictive features of regression have been identified, with the possible exception of initial size <62 mm.[278] Rare reports of malignancy have led some to suggest that these lesions should be removed if they persist, and only lesions that involute be managed non-operatively.[279,280] More recently, it is recognized that the likelihood of malignancy is extremely rare.[281] Rarely, lesions that compromise respiration or feeding, or are associated with hypertension, should also be excised.[282]

Bilateral cystic lesions

Autosomal recessive polycystic kidney disease (ARPKD) is an inherited nephropathy with an overall incidence of approximately 1:20 000 and presents with varying degrees of severity.[283] Children present with massively enlarged kidneys that are typically seen on antenatal or postnatal sonograms as homogeneously hyperechogenic. In severe cases oligohydramnios and Potter's facies may be present. The

sonographic pattern is sufficiently different from that of MCDK and autosomal dominant polycystic kidney disease (ADPKD) to distinguish reliably between these. Pathologically the kidneys of these children exhibit ectasia and cystic dilatation of the collecting tubules. Associated conditions include pulmonary hypoplasia and hepatic fibrosis, which both contribute significantly to morbidity. Abnormalities of the the ARPKD gene, *PKHD1*, are responsible for this disease. Prognosis for these children depends on the spectrum of their disease, but is generally poor, with those surviving the neonatal period requiring hemodialysis and transplantation.[284] Up to 30% of children die as neonates, with 20–45% progressing to end-stage renal disease by age 15.[285]

ADPKD has an incidence of 1 in 500 to 1 in 1000 births, and two gene sequences on chromosome 16 (*PKD1*) and chromosome 4 (*PKD2*) have been associated with this disorder.[286,287] Approximately, 85% of cases are related to an abnormality of *PKD1*.[288] A third locus, *PKD3*, has been proposed but remains unidentified.[288] Although formerly called 'adult' polycystic kidney disease, this name is inaccurate as the condition has been identified in children. Patients with this disease may be diagnosed by prenatal sonogram. Sonography is also the primary modality used to screen potentially affected siblings.[289] Infants born with this disorder often have massive renomegaly and severely affected infants have poor survival. It is important to remember that in children the disease may initially present unilaterally or with asymmetry. A meta-analysis of the cases identified in utero revealed that 43% of cases died before the first year of life and a significant proportion (67%) developed hypertension by age 3.[290] Children who do not present in the neonatal period often come to attention later in life with hypertension, impaired renal function, proteinuria, or hematuria. Associated conditions include hepatic and pancreatic cysts as well as cerebral aneurysms. Although the outlook for these patients is improving, a significant number eventually develop renal failure.[291]

Midline cystic abdominal lesions

As with UPJ and MCDK, modern ultrasonography has greatly facilitated the diagnosis of other less common cystic abdominal masses in infants. Previously, children would often undergo laparotomy to establish such a diagnosis.

Hydrometrocolpos refers to the distention of the vagina with mucus and blood derived from uterine and cervical glands. Produced in response to maternal estrogens, it results from vaginal obstruction secondary to imperforate hymen or other obstructive vaginal anomalies such as transverse vaginal septum, or vaginal atresia.[292] In patients with a mid or high transverse septum or vaginal agenesis, a thorough search for associated genitourinary and gastrointestinal abnormalies should be performed.[293] It most commonly presents as a midline abdominal mass and/or an interlabial mass in the perineum, which is the bulging imperforate hymen. The diagnosis has also been made on antenatal sonography.[294,295] Careful physical examination will show that the mass is anterior to the rectum. Sonography will indicate that the lesion is behind the bladder. A common finding in these patients is lower urinary tract obstruction and hydronephrosis.[296] Once the diagnosis is made, incision of the hymen and drainage result in resolution of the mass. Hydronephrosis then usually resolves with time. Care must be taken because simple percutaneous drainage may result in reaccumulation of secretions within the vagina. Serial ultrasonography should be performed to ensure that the hydronephrosis resolves. Other causes of an interlabial mass in a newborn infant include hydro(metro)colpos, prolapsed urethra, prolapsed ureterocele, and paraurethral cyst.

Ovarian cysts are the third most common cause of an intra-abdominal mass in an infant, after renal and gastrointestinal causes. They may exist in up to 30% of neonates.[297] This diagnosis has been made prenatally by ultrasound as well as postnatally.[298] The classic prenatal sonographic appearance is that of an anechoic, unilocular mass in the fetal pelvis. Any internal echogenicity suggests cyst torsion or hemorrhage.[297] The majority of cysts regress and only require observation. Large cysts may compromise bowel or respiratory function. Adnexal torsion in females followed by cystic degeneration of the ovary may occur. This situation is typically managed by excision of the cystic mass (Figure 6.20). This can be accomplished by open surgery or may be achieved laparoscopically, even in infants[299] (Figure 6.21) .

Dilation of the urinary bladder or megacystis can also result in an abdominal mass. It is most typically associated with posterior urethral valves in male infants. The classic US findings include a dilated, thickened bladder and a dilated posterior urethra ('keyhole sign'). Other potential causes include urethral atresia, megacystis-microcolon syndrome, prune belly syndrome, and ureterocele obstructing the bladder outlet. Neonatal urinary ascites previously

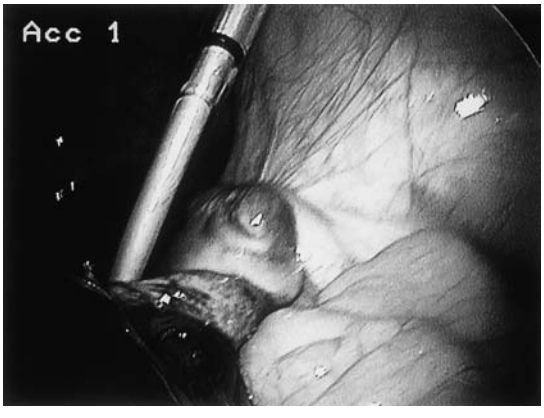

Figure 6.21 Laparoscopic identification of ovarian torsion.

presented as an enlarged abdomen in newborns; however, today the diagnosis is frequently made in utero by antenatal sonography.[300,301] Ascites in the fetus or newborn can be from urologic and non-urologic causes. *Urinary ascites accounts for about 30% of all cases of neonatal ascites*.[302] Among urologic causes, lower urinary tract obstruction and trauma are most common. Specifically, PUV, urethral stenosis, distal ureteral stenosis, and obstructing ureteroceles have all been associated with neonatal urinary ascites[302–307] (Figure 6.22). Less frequently, obstructed and hydronephrotic kidneys may also be the cause. In these cases, extravasation of urine occurs either from the bladder or, more commonly, from a forniceal rupture in the kidney.[309] Ascites from unilateral obstructive lesions has been reported, although far less commonly than in cases of bilateral obstruction.[310] Alternatively, perinatal trauma to the urinary tract may also cause neonatal ascites.[311] In particular,

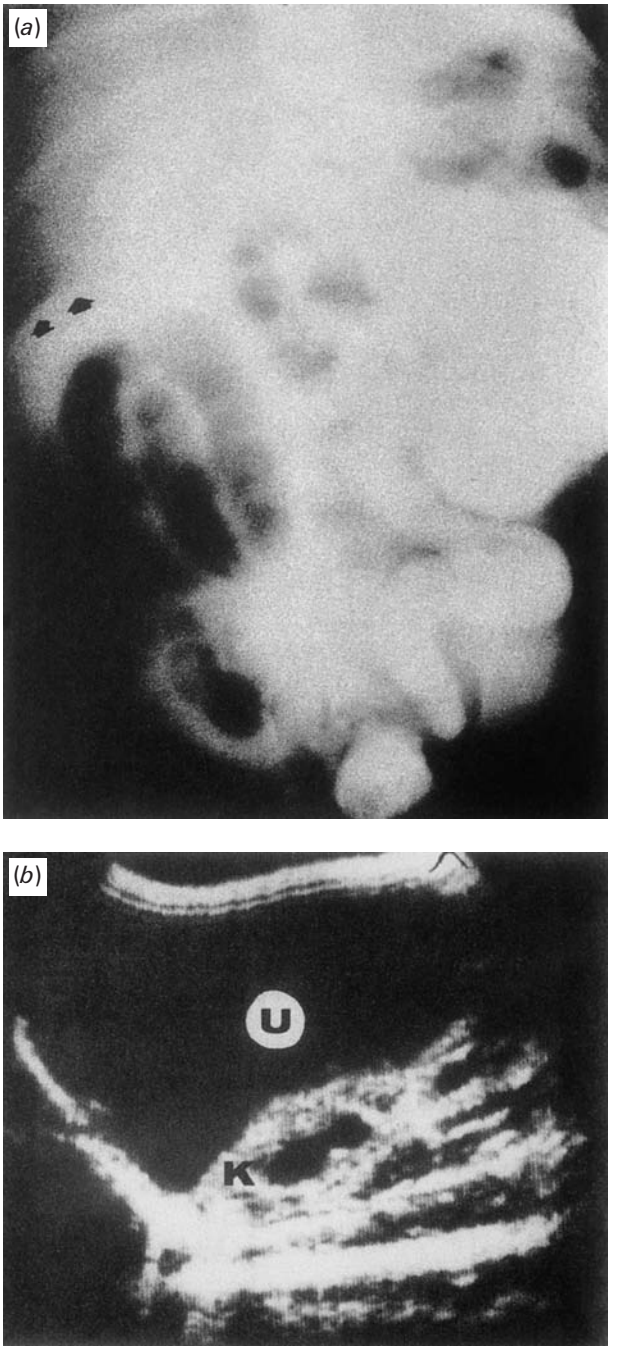

Figure 6.22 (*a*) Voiding cystourethrogram of urinary ascites: the black arrows point to the liver edge. (*b*) Ultrasound study showing a retroperitoneal urinoma. K, kidney; U, urine collection. (From Rittenberg et al,[308] with permission.)

umbilical artery catheterization with inadvertent bladder perforation is an important cause of neonatal urinary ascites.[312,313]

Sonography and VCUG can usually determine the urologic abnormality and site of extravasation in those with neonatal urinary ascites. Historically, plain

film X-ray findings of a ground-glass appearance of the abdomen with floating loops of bowel have been described in patients with ascites. Neonatal urinoma, which may or may not be associated with ascites, can be identified by a 'c' sign, a rim of opacified contrast around the kidney on intravenous pyelography (IVP).[314] Clinically, these patients can be quite ill. The characteristic laboratory findings include hyponatremia, hyperkalemia, and elevated serum creatinine.[315] Treatment is individualized, but urinary drainage with a urethral catheter allowing the intraperitoneal urine to be reabsorbed, along with urinary antibiotic prophylaxis, is often sufficient. Open drainage may be required in instances where infection of the urine occurs or when respiratory embarrassment is due to the mass effect. Previous reports of 70% mortality have improved to less than 15% in more recent series.[307,316,317] Recently, De Vries et al[318] reported long-term follow-up of a series of patients with severe obstruction that had good lower tract and renal function. Like others, the authors postulate that the development of ascites serves as a protective mechanism, allowing the kidney to decompress and minimizing damage from obstruction.[319–321] Non-urologic causes of neonatal ascites include erythroblastosis fetalis, cardiac or hepatic abnormalities, sepsis, and gastrointestinal perforation.[259]

Solid lesions

Solid lesions in children are being detected prenatally with increasing frequency. One of the best examples is neuroblastoma.[322,323] Whereas early detection of neuroblastoma does not necessarily change initial management, it results in the child receiving treatment sooner. In addition, patients with neuroblastomas detected early in life have a better outlook. Thus, early diagnosis probably improves the prognosis.[322] As a rule, solid lesions detected antenatally are followed before delivery, and then after birth are imaged by computed tomography (CT) scan or MRI. Occasionally, a postcontrast kidney, ureter, and bladder (KUB) film may clarify the diagnosis. No indications for antenatal intervention exist for solid lesions.

Sacrococcygeal teratoma represents the most common fetal neoplasm, with an estimated incidence of 1 in 40 000 births.[324] The majority occur in females. Intrapelvic lesions may be difficult to diagnose. The presumptive in-utero diagnosis has been made by ultrasound. When this lesion is suspected in the postnatal period it is best evaluated by CT or MRI.[325] The tumor may cause obstruction of the urinary tract with resultant hydronephrosis. Treatment typically consists of surgical excision

Neuroblastoma is the most common solid malignant tumor in neonates and is characterized by its variability in presentation.[326] This tumor effects 1:7000 children, with 40% of cases diagnosed in children <1 year of age.[327] The tumor is often identified prenatally.[328–331] In addition to prenatal ultrasound, fetal MRI can contribute to the prenatal evaluation.[332] Many factors, including age at detection and location, affect overall outcome. Early diagnosis and treatment may be critical in some cases.[333] However, information derived from countries with mandatory postnatal screening for neuroblastoma suggests that many tumors detected in the perinatal period regress. Therefore, some infants diagnosed very early may have unnecessary interventions.[334–336] More recently, well-designed studies have demonstrated that neonatal screening is unlikely to effect mortality in neonates.[327] The Children's Oncology Group currently is conducting an observation pilot study for children presenting with perinatal neuroblastoma. Specific inclusion criteria are: age <3 months; sonographically identified adrenal mass, which is <16 ml in volume, if solid, or <65 ml if at least 25% cystic, and which does not cross the midline.

On physical examination, neuroblastoma has been classically described as a firm, fixed lesion that may cross the midline. Children may also present with bulky metastatic disease that includes a palpable liver and subcutaneous nodules that characterize stage IV-S disease. This form usually undergoes spontaneous regression.[337] Imaging by ultrasound can usually suggest the diagnosis. Confirmation is made by CT scan or MRI. These studies show a lesion that displaces the kidney but does not arise from the kidney (Figure 6.23). The appearance of a tumor arising from the kidney will cause a beaking effect of the renal tissue (Figure 6.24). Despite modern imaging techniques the diagnosis of neuroblastoma may be confused with other less common conditions, such as pulmonary sequestration.[338] Cystic neuroblastomas detected prenatally have also been reported, so the diagnosis should not be excluded on the basis of a cystic component.[339–343] Most neuroblastomas cause elevations of urinary catecholamines, which should be checked in all such patients.

Treatment varies from observation to surgery for those patients with early-stage localized disease. Multimodal therapy, including chemotherapy and radiotherapy, is indicated in patients with advanced

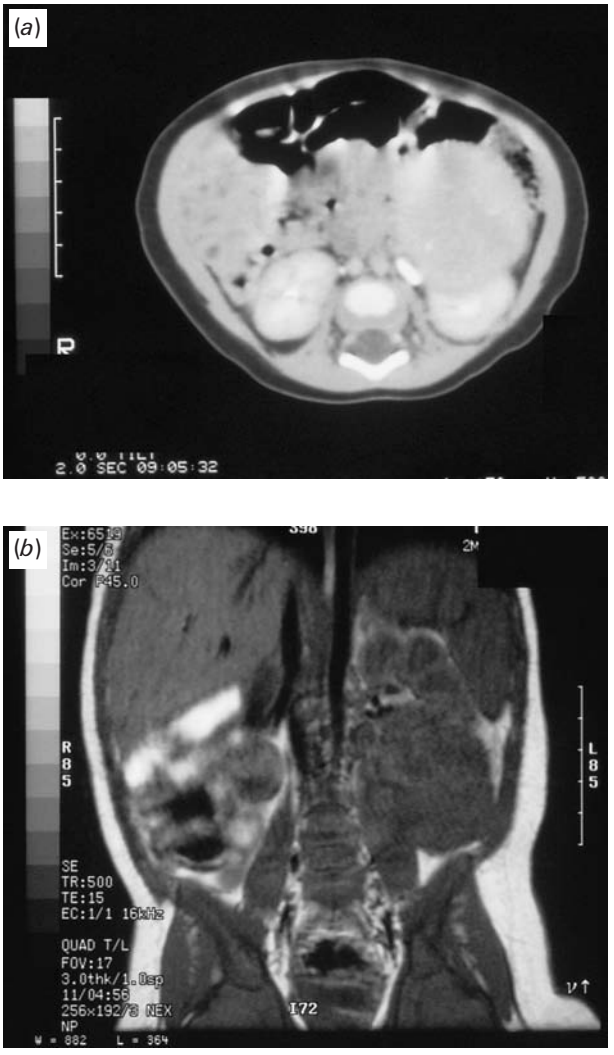

Figure 6.23 (*a*) CT scan showing displacement of the kidney by neuroblastoma (note no beaking of the renal tissue). (*b*) MRI showing neuroblastoma in relation to the kidney. (*c*) MRI showing normal renal contour confirming that the tumor is separate from the kidney.

disease. There are several clinical trials of experimental drugs in the high-risk group. Treatment protocols are available through the Children's Oncology Group.[333,334]

Although Wilms' tumor is the most common renal tumor in children, it occurs infrequently in the neonatal period.[345] In children <6 months of age, congenital mesoblastic nephroma is a more common cause of a solid renal lesion; however, Wilms' tumor, rhabdoid tumors, clear cell tumors, renal cell carcinoma, angiomyolipoma, and ossifyng tumors are known to occur.[346,347] Most of these present as a neonatal abdominal mass, less frequently as hematuria, paraneoplastic syndromes, or hypertension.[348] Wilms' tumor has also been detected by prenatal US evaluation.[349–351] Associated findings in the prenatal period include fetal hydrops and polyhydramnios.[348] Postnatally these children may have a palpable mass and in some cases hypertension. Children born with known associated syndromes such as aniridia, WAGR syndrome, Denys-Drash symdrome, or Beckwith–

Wiedemann syndrome develop tumors at a younger age and are more likely to have bilateral lesions; therefore surveillance US should be performed.[345] Bilateral nephroblastomatosis, aniridia, and 11p13 deletion result in the development of Wilms' tumor in close to 100% of affected individuals (Figure 6.25). These patients may develop bilateral Wilms' tumor, requiring nephron-sparing surgical techniques. Evaluation of the vascular anatomy is best performed with MR angiography[352] (Figure 6.26). The treatment is based on stage of the tumor and involves surgery, chemotherapy, and sometimes radiation therapy. The common chemotherapy agents utilized include vincristine, doxorubicin, and dactinomycin. Readers are referred to the Children's Oncology Group protocols for specific therapy recommendation.

Congenital mesoblastic nephroma is a rare renal tumor that is the most common solid renal mass in children <6 months of age (50%). Eighty percent of these lesions are discovered in the first month of life.[353] Congenital mesoblastic nephroma may frequently be detected prenatally, where it is associated with polyhydramnios in approximately 70% of cases.[354] Typically, the lesion is noted as a solid intrarenal mass on sonogram that appears fibroid when removed[355] (Figure 6.27). A cystic form can also occur[353] (Figure 6.28). Pathologically, the tumor can be divided into two groups: classic and cellular. The classic lesion represents one-third of cases and is microscopically similar to a leiomyoma and does not metastasize.[356,357] The cellular variant has the potential for local recurrence and metastasis.[348,357] In-utero treatment usually consists of observation and management of polyhydramnios with its attendant complications. Postnatally, nephrectomy is recommended. In cases where metastases have occurred, chemotherapy may be warranted.[348,358] Hypercalcemia requiring treatment has been documented but usually resolves after nephrectomy.[348] Cases requiring urgent surgery following tumor rupture and hemorrhage have been reported.[359,360]

Renal vein thrombosis (RVT) may be the cause of a mass in a neonate. The characteristic clinical presen-

tation of RVT – an enlarged kidney, hematuria and proteinuria in an ill infant – is only present in a small percentage of patients (Figure 6.29). Low platelet counts due to consumption by the developing thrombus may be seen. Infants appear to be predisposed to this condition, because of lower renal arterial and venous flow rates, than older children and adults. Reports of prenatal diagnoses of RVT are now commonplace.[362,363] RVT is most commonly associated with risk factors that include dehydration, sepsis, birth asphyxia, maternal diabetes, polycythemia, cardiac disease, protein C deficiency, twin-twin transfusion, and presence of an umbilical catheter.[363] In addition, the significance of prothrombotic risk factors, such as factor V, are increasingly being recognized.[364,365] The thrombosis starts in the venules within the kidney and progressively extends to the major renal vein or veins. The diagnosis is most commonly made by ultrasound (Figure 6.30). Initially, the lesion appears as highly echogenic streaks within the kidney. Subsequently, the kidney becomes enlarged and echogenic, with loss of corticomedullary differentiation.[361] Treatment of unilateral RVT is supportive, with hydration and correction of any predisposing abnormalities.[366] Bilateral thrombosis requires more aggressive treatment and has a worse prognosis, but thrombus removal has not proven helpful. These patients warrant treatment with either heparin or systemic thrombolytic therapy in order

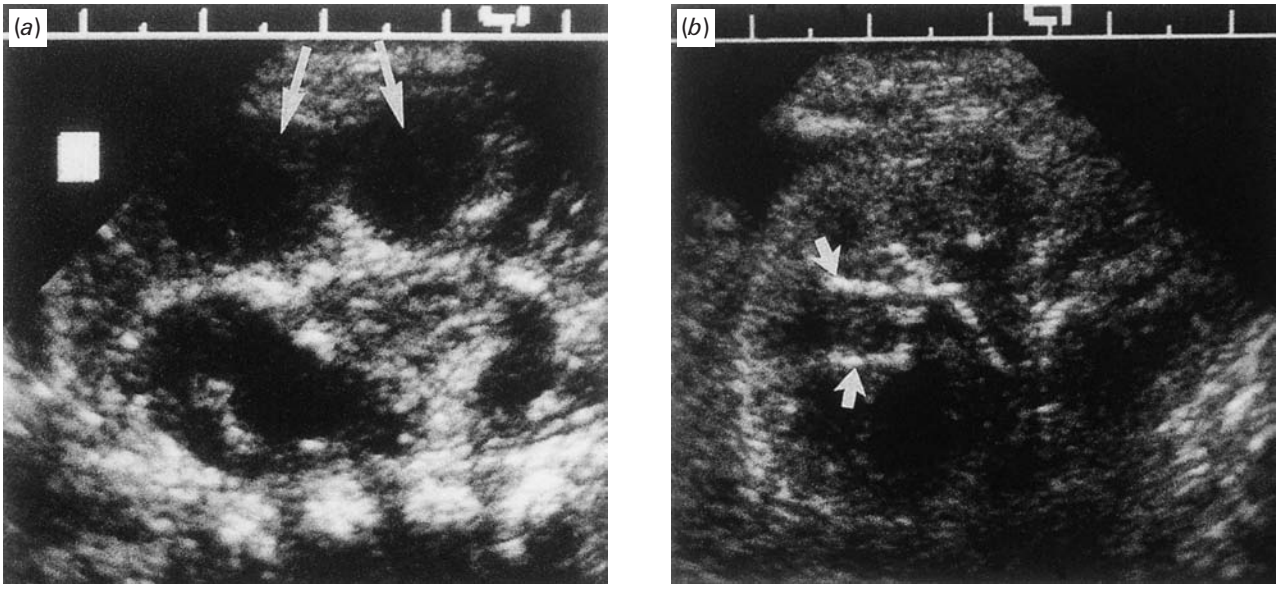

Figure 6.29 Renal vein thrombosis. (*a*) Enlarged left kidney with echogenic intermedullary streaks and echopoor medullary pyramids (arrows). (*b*) Same patient's right kidney showing swelling of the upper pole and focal echogenic intermedullary streaks. (From Hibbert et al,[361] with permission.)

to minimize morbidity.[367,368] Recent reports suggest that those who receive aggressive therapy with anticoagulants fare better than those who do not.[363] Patients with unilateral thrombosis usually do well, whereas those with bilateral thrombosis have a higher rate of complications such as renal failure.[369] All patients must have long-term monitoring of renal function and evaluation for hypertension, which is common.[370,371]

Renal artery thrombosis does not commonly present as a neonatal mass.[372] The occurrence of this disorder has increased significantly in relation to the increased use of umbilical artery catheters, despite the fact that a causal relationship was identified some time ago.[373] The diagnosis is commonly made with Doppler ultrasound, which demonstrates the absence of flow in the renal artery. Treatment options include supportive measures, thrombolytics, and surgery, depending on the extent of thrombosis and whether or not aortic involvement exists.[374–377]

Neonatal adrenal hemorrhage is associated with traumatic or difficult labor, neonatal hypoxia, septicemia, or coagulopathy. Traditionally, it is believed that the relatively large size and vascularity of the newborn gland predisposes it to bleeding. A study using ultrasound to screen newborns for adrenal hemorrhage in 8374 pregnancies reported an incidence of 1.9 per 1000 births.[378] In this report, 13 cases were on the right, two on the left, and one was bilateral. These findings corroborate previous reports indicating a right-sided predominance and 10% bilaterality. Diagnosis is made by ultrasound, and antenatal diagnosis has been made in the second and third trimesters (Figure 6.31). Identification by ultrasound is usually reliable, but in some cases it is difficult to differentiate from an adrenal neuroblastoma[379–381] (Figure 6.32). In difficult cases, CT and MRI may be helpful in the diagnosis.[382,383] Negative urine catecholamines also support the diagnosis of adrenal hemorrhage.

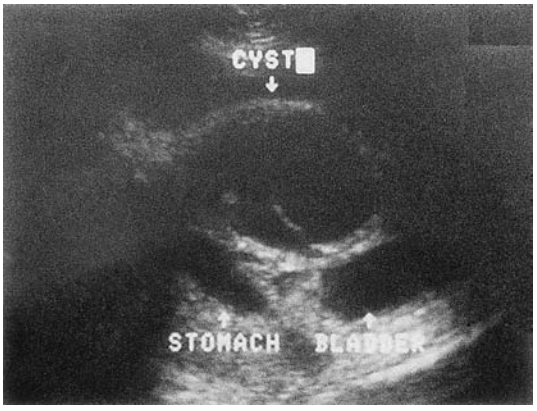

Figure 6.31 Prenatal adrenal hemorrhage identified as a complex cyst on sonogram. (From Burbige,[379] with permission.)

Experience has confirmed the initial belief that the majority of infants with adrenal hemorrhage require no treatment except for occasional phototherapy and, rarely, transfusion.[384,385] Resultant adrenal insufficiency is uncommon. Observation for resolution and monitoring of hematocrit and bilirubin should be routine. Occasionally, steroid replacement for temporary adrenal insufficiency is required.

Cystic nephroma is a rare benign renal neoplasm. Lesions may be unilateral or bilateral, and bilateral metachronous lesions have been reported.[386] Partial nephrectomy is appropriate when possible to preserve renal parenchyma (Figure 6.33).

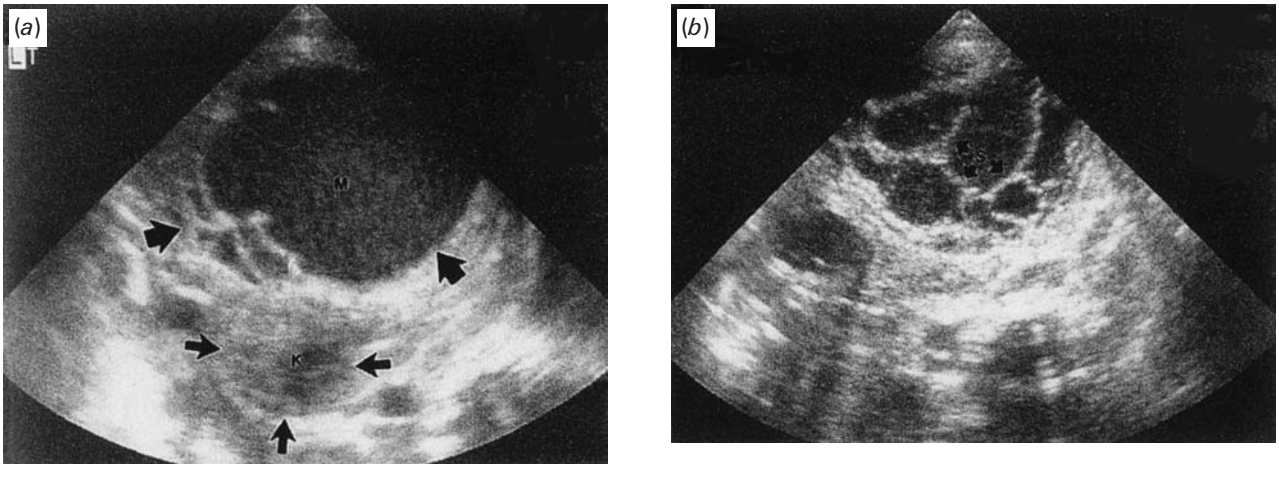

Figure 6.32 Postnatal confirmation of a complex cystic lesion superior to the kidney. Surgical exploration later confirms adrenal hemorrhage. (From Burbige,[379] with permission.)

(*b*) CT scan of the same patient 2 years later with a solitary right kidney and metachronous cystic nephroma. (From Ferrer and McKenna,[386] with permission.)

Rhabdomyosarcoma is an uncommon neoplasm of the lower urinary tract in children. Lesions may occur in the bladder, prostate, vagina, or uterus (Figure 6.34). Presentation in infancy depends on the organ of origin and may include hematuria, vaginal bleeding, or obstruction of the urinary tract. Treatment is multimodal, including chemotherapy, radiation therapy, and exenteration followed by reconstructive surgery.[387,388] As a result of collaborative efforts by the Intergroup Rhabdomyosarcoma Study, treatment results for these patients are improving. Current efforts are focused on bladder preservation.[389] Dysfunctional bladders may result, however, from high doses of chemotherapy and radiation.

Germ cell tumors are rare in children and their presentation as a lower abdominal mass is extremely uncommon. They may occur as an ovarian mass or as a mass in an undescended testis.[390,391] Treatment for these tumors is dependent on stage at diagnosis but is usually multimodal including surgery and platinum-based chemotherapy, depending on histology.

Enterocystoplasty and the acute abdomen

Bladder augmentation with bowel segments is commonly performed in children with neuropathic bladders, bladder tumors, and exstrophy. Most of these patients require clean intermittent catheterization after bladder augmentation and have poor bladder sensation. A combination of poor sensation and overdistention can lead to a spontaneous augmentation rupture, an acute abdomen, and life-threatening sepsis. The presentation can be confusing because most patients have altered abdominal sensation, so identifying the source of sepsis can be difficult. A cystogram may not reveal extravasation and the best rapid screening study may be a sonogram that shows floating loops of bowel. Early surgical exploration is indicated. The rupture is usually located at the posterior suture line between the bladder and augmented bowel. Whenever a patient with a bladder augmentation presents with sepsis, this diagnosis should be considered.

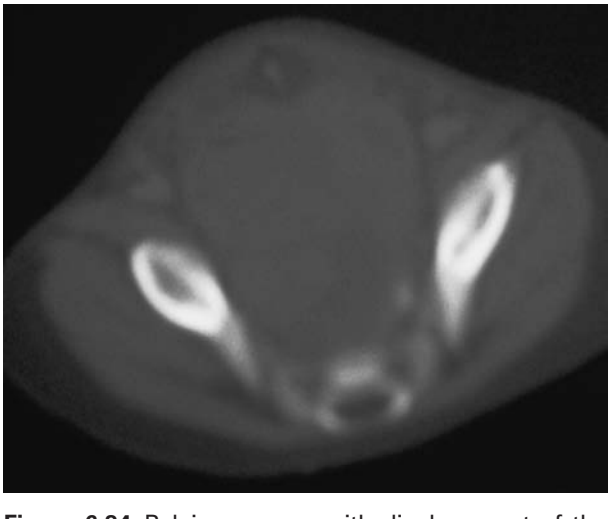

Figure 6.34 Pelvic sarcoma with displacement of the bladder superiorly. Note Foley balloon in the bladder.

Intraoperative consultations

The best approach to intraoperative consultations is to take the time to obtain a complete history. This is usually chart based but may include talking to the parents prior to making a quick decision about a complex question. This is also the case when one is asked about a surgical finding or called to address a surgical complication. After the chart review and appropriate history, it is best to scrub into the case and review the exact location of the lesion from the skin to the region of question. One must take a fresh look at the situation and not rely totally on the primary physician. When any questions arise that deal with surgical excision of a mass, multiple radiologic modalities can be used intraoperatively, and frozen section sampling is available. There is little to be lost in closing the patient who needs further evaluation, which cannot be undertaken in the operating room, and reoperating when the problem is better understood.

Many unusual structures may be found during a pediatric hernia repair. Among these is the finding of reproductive organs appropriate to the opposite sex. Although rare, this will usually generate an intraoperative consultation. In males, the finding of female organs, such as a fallopian tube or uterus, is termed persistent Müllerian duct syndrome[392] or hernia uterine inguinale. The cause of this anomaly is a failure of Sertoli cell production of Müllerian inhibiting substance (MIS), leading to feminization of pelvic structures. The testis should be undescended, but otherwise the patient is phenotypically male. Intraoperative biopsy confirms the presence of a normal testis. Excision of the female structures should be performed with care, avoiding injury to the adjacent functioning Wolffian duct structures. Excision is important because of the risk of future malignancy arising in these tissues.[393] Others have recommended that they be left in place to avoid potential injury.[394] In phenotypic females, the finding of male reproductive structures during hernia repair suggests testicular

feminization. Here, the timing of excision of the male gonads is controversial: if removed early, exogenous estrogens must be administered to induce normal maturation at puberty; if left in situ until puberty, the testis must then be removed because of the high possibility of developing gonadoblastoma.[395] Laparoscopic removal of the testis allows for a minimally invasive approach yet permits direct molecular analysis of the specimen.[396] Over 40 other tissues have been identified in and around the hernia sac. They include normal structures drawn into the sac, organ duplications as 'rests', inflammatory lesions, tumors, and drainage from the abdomen into a patent processus vaginalis.[397]

1 Organs drawn into the hernia sac:
   - appendix
   - bladder
   - gonad
   - Meckel's diverticulum
   - omentum
   - bowel
   - pelvic kidney
   - ureter
   - uterus.
2 Aberrant rests:
   - adrenal
   - ectopic renal tissue
   - accessory spleen.
3 Inflammatory lesions:
   - abscess
   - funiculitis
   - granulomas
   - sarcoidosis
   - meconium granuloma
   - parasitic disease
   - peritonitis
   - polyarteritis nodosa
   - vasitis nodosa
   - xanthogranuloma.
4 Tumors and benign lesions:
   - adrenal tumor
   - dermoid cyst
   - epidermoid cyst
   - epididymal cysts and nodules
   - calculi
   - hemangioma
   - lymphangioma
   - mesenchymoma
   - neuroblastoma
   - paratesticular cyst/rhabdomyosarcoma
   - spermatic cord tumors
   - spermatocele
   - tunica albuginea cyst
   - tunica vaginalis cyst
   - venous thrombosis
   - Wilms' tumor.
5 Lesions that appear because of patent processus vaginalis:
   - adrenal hemorrhage
   - endometriosis
   - meconium
   - blood.

Unusual findings in the spermatic cord of which the urologist should be aware include those listed above, particularly ectopic adrenal tissue and accessory spleens.[398,399] In cases of ectopic adrenal tissue the yellow color and an appearance similar to the normal gland usually aid identification. Neuroblastoma has also been reported to present as a mass in the spermatic cord.[400] In addition to the more common scrotal masses, heterotopic Wilms' tumor and neuroblastoma have been reported.[401] Both adrenal and splenic tissue have also been found in the scrotum, and splenogonadal fusion is not uncommon with an undescended left testis. Excision of these masses is usually best, with careful pathologic evaluation to confirm the diagnosis.

Although vasal injuries are most commonly diagnosed later in life during the work-up of infertility, vasal injury during pediatric hernia repair mandates intraoperative pediatric urologic consultation. Previous studies have documented the ease with which vasal trauma may occur secondary to intraoperative manipulation.[402] In cases of transection, immediate microvascular repair is indicated. Crush injuries may result in future obstruction. In these situations the decision regarding treatment must be individualized. In most instances observation is indicated. However, when a severe crush injury has occurred, as when a clamp is applied and closed with obvious injury, excision and primary reanastomosis is indicated.

Intraoperative consultations relating to the bladder are usually a result of trauma or iatrogenic injury during surgery. Intraoperative injury to the bladder is rare but may occur secondary to percutaneous laparoscopic procedures or during inguinal hernia repair. When it happens it is best managed by primary closure, and bladder drainage in the postoperative period via a urethral catheter and/or suprapubic tube. Perivesical drainage is also appropriate in the immediate postoperative period. A cystogram to confirm the absence of extravasation should be performed

prior to removal of drainage catheters. Rarely, during umbilical hernia repair, a urachal abnormality is discovered. In these cases the urachus should be traced to the dome of the bladder and excised with primary closure of the bladder.[401] If the diagnosis is uncertain, an intraoperative cystogram may clarify the picture.

Most consultations related to the kidney and ureter are in patients with renal trauma. *The basic recommendation is not to explore the flank even when an expanding mass is present until normal function of the contralateral kidney has been assured.* When an expanding retroperitoneal mass is explored after trauma, early renal vascular control should be the main objective. Traumatic separation of the ureter and pelvis occasionally occurs in children. Unlike many injuries where drainage and observation is indicated, complete avulsion of the ureter should be surgically repaired as quickly as possible. It is a more complex procedure than a standard UPJ repair because the pelvis is almost always intrarenal and mobilization of the kidney and ureter to prevent tension on the anastomosis can be difficult. The procedure is much more difficult if the correction is delayed because of edema with subsequent scar formation.

As a result of advances in imaging and thorough preoperative evaluations, consultations because of a previously undiagnosed renal mass, formerly common, are now unusual. Despite this, the urologic surgeon should bear in mind that occasionally an ectopic or a pelvic kidney may be confused with a pelvic mass and indicate intraoperative consultation. Reports of inadvertent nephrectomy in patients with solitary ectopic kidneys are found in the literature.[401] When it is unclear whether the mass in question is a solitary kidney, intraoperative imaging may be necessary to clarify the situation. This is critical, as reports indicate that up to 10% of all pelvic kidneys are solitary.[403] Intraoperatively, it is important to remember that ectopic kidneys may not be reniform in shape and tend to have an anomalous blood supply derived from the aorta and iliac vessels, or the superior mesenteric artery.[403] Simple needle aspiration to confirm the presence of urine may also be useful in identifying a kidney. Fusion anomalies and horseshoe kidneys may also be a source of confusion and prompt urologic consultation.

Occasionally, the urologist will be called to evaluate an infant for difficulty in placing a urethral catheter. Initially, properly lubricating the urethra by injecting 2% lidocaine jelly facilitates catheter insertion. Most commonly, these will be male neonates who have had multiple attempts at catheterization before urologic consultation. In these cases a good option may be to use a curved-tip 'coude' catheter, which has recently become available in pediatric sizes. When these catheters are not available, or will not pass, a small catheter guide may be placed within a pediatric feeding tube and manipulated into the bladder. If no guides are available, bending a heavy wire suture for use as a catheter guide may be successful.[404,405] Lubricating jelly must be placed on the guide to facilitate its removal. In cases where this fails, proceeding directly to cystoscopy to evaluate the possibility of a false passage is warranted. Use of a guidewire placed under direct vision followed by catheter placement over the wire ensures proper catheter placement. When the bladder is palpable, a percutaneous cystotomy may be performed under local anesthesia or in the operating room. Alternatively, a large-gauge needle placed into the distended bladder will permit insertion of a guidewire, dilation of the tract, and placement of a suprapubic catheter.

Urinary tract infections in children 7

Hans G Pohl and H Gil Rushton

Introduction

In prior editions, this chapter was introduced with the concept that recently discovered bacterial virulence factors, such as those promoting adherence to uroepithelial cells, were assuming a greater importance in the pathophysiology of urinary tract infections (UTIs) in children. However important these genetically encoded bacterial factors might be in enhancing the potential of uropathogenic bacteria to cause symptomatic disease, mounting evidence suggests that deficient host defense factors and tissue repair mechanisms may contribute more significantly to an individual's susceptibility to urinary infection.

Epidemiology

Urinary tract infections in children may be symptomatic or asymptomatic. Symptomatic infections may be confined to the bladder (cystitis), or they may involve the upper collecting system (ureteritis, pyelitis), or extend into the renal parenchyma (pyelonephritis). Age, gender, race, circumcision status, the method of detection, and presentation all influence the prevalence of symptomatic versus asymptomatic urinary infection.

Overall, the incidence of neonatal bacteriuria has been reported as 1–1.4%.[1–3] The male-to-female ratio in infants is reversed from that seen in older children. From a compilation of screening studies of healthy newborns reviewed by Stamey, 1.5% of boys versus only 0.13% of girls had bacteriuria.[4] However, the actual incidence of UTI during infancy has probably been underestimated in the past, partly because of the difficulty in diagnosing UTI in this age group. In a 3-year prospective study of 3581 infants (aged 0–1 year) in Goteborg, Sweden, asymptomatic bacteriuria was confirmed by suprapubic aspiration of urine in 2.5% of boys and 0.9% of girls.[5] Symptomatic urinary infection occurred equally often in both sexes (1.2% of boys and 1.1% of girls). Overall, 3.7% of boys and 2% of girls had positive urine cultures during the first year of life. The male predominance noted in the Goteborg study during the first few months of life has also been reported by others.[6–9] Uncircumcised infant boys are eight to ten times more likely to have symptomatic urinary infection as compared to their circumcised counterparts.[10]

During preschool and school age, the male-to-female ratio observed in neonates is reversed, making screening bacteriuria more prevalent in girls[8,9] (Table 7.1). In several large studies of school-age children the aggregate risk of screening bacteriuria has been reported to be 0.7–1.95% of girls and 0.04–0.2% of boys.[12–16] However, in as many as one-third of these children a prior history of UTI or voiding symptoms could be elicited (Table 7.2). Based on an average annual incidence figure of 0.4%, Kunin (1964) estimated that bacteriuria will develop in approximately 5% of girls prior to graduation from high school. Additional data collected by Kunin[12] revealed that infection will recur in up to 80% of all white girls and 60% of black girls within 5 years of initial infection.[12]

In a prospective population-based study of symptomatic UTIs in children living in Goteborg, Sweden, Winberg et al estimated that the aggregate risk for symptomatic UTI up to age 11 was at least 3% for girls and 1.1% for boys.[11] In an update of a previous study, the incidence of culture-documented UTIs was

Table 7.1 Gender ratio of urinary tract infections

Age range	Females	Males
Neonate	0.4	1
1–6 months	1.5	1
6–12 months	4.0	1
1–3 years	10.0	1
3–11 years	9.0	1
11–16 years	2.0	1

From Belman and Kaplan, 1981, modified from Winberg et al.[11]

Table 7.2 The clinical history and symptoms of 109 children with 'screening' bacteriuria

History/symptoms	Prevalence (%)
All symptoms (excluding nocturnal enuresis)	70
Urgency	54
Frequency	53
Nocturnal enuresis	51
Diurnal enuresis	47
Previous urinary tract infection	20
Dysuria	13
Unexplained fever	7
Flank pain	4
Nocturia	4

Modified from Savage et al.[17]

twice as high as previously estimated, affecting 7.8% of girls and 1.6% of boys during the first 6 years of life.[18] To confirm these findings, Marild and Jodal recently performed a retrospective population-based study of 41 000 children of Goteborg, Sweden.[19] The cumulative incidence rate of symptomatic UTIs was 6.6% for girls and 1.8% for boys. These data probably do not reflect an increasing incidence of UTIs since the publication of the earliest report, but instead a greater detection rate. In these epidemiologic studies, the incidence of febrile UTIs was greatest in infant boys and girls as compared to children over 2 years of age. Gender differences in the incidence rates of first-time febrile and non-febrile UTIs were most evident in children >2 years old. Girls >2 years old were much more likely to present with first-time UTI, both with and without fever, as compared to their age-matched male counterparts (Figure 7.1a and b).

Once treated, infants with symptomatic urinary infections are at risk for recurrent infection (26%), usually in the first 3 months of follow-up. In older girls the risk for recurrence following symptomatic

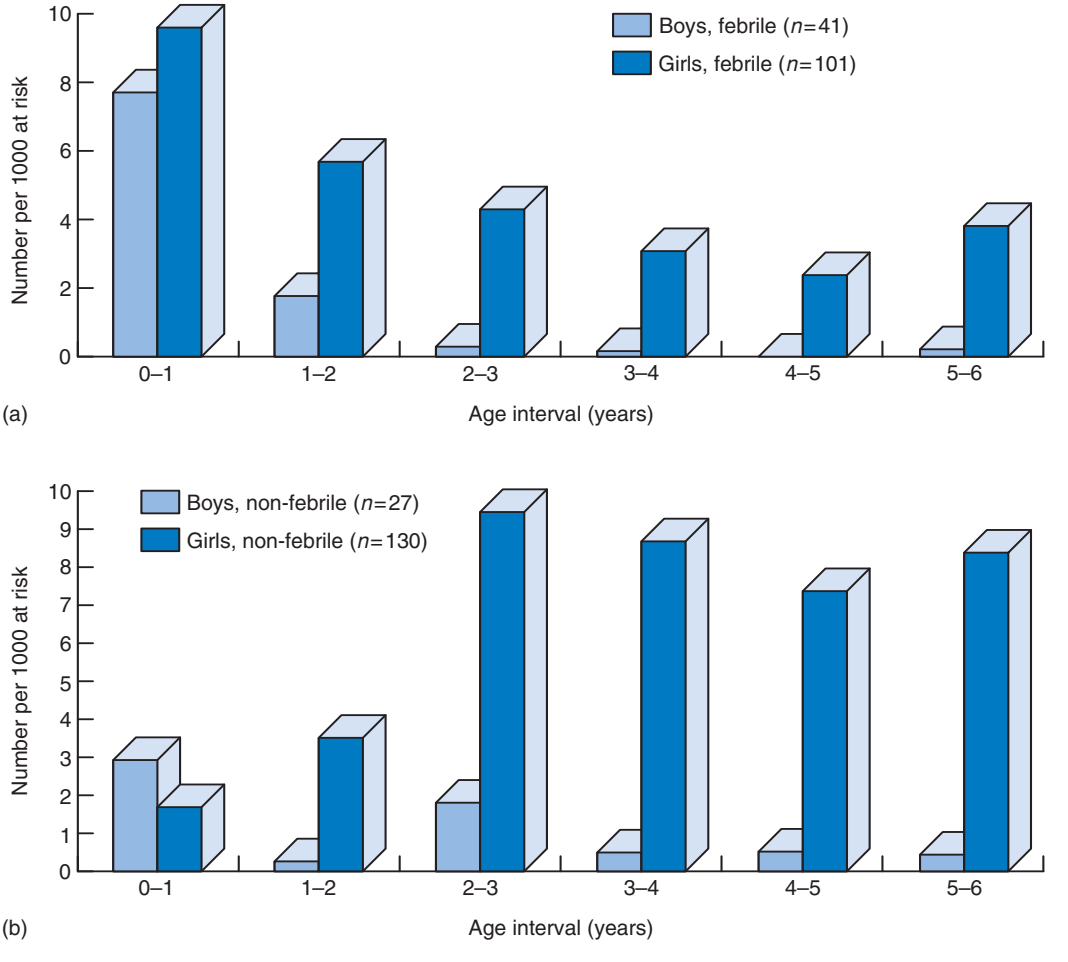

Figure 7.1 Annual incidence rate in 1 year intervals of febrile urinary tract infection in children studied during a 20-month period between 1979 and 1981. (*a*) Incidence of febrile infections in boys compared with girls. (*b*) Incidence of non-febrile infections in boys compared with girls. (Adapted from Marild and Jodal.[19])

urinary infection is as high as 40–60% within 18 months. This risk persists into adulthood.[8] In one study, 60 girls with childhood bacteriuria followed into adulthood (9–18-year follow-up) were compared with 38 non-bacteriuric controls.[20] During pregnancy, a significantly greater incidence of bacteriuria was diagnosed in the group with the history of positive urine cultures in childhood (63.8%) when compared with the controls (26.7%). Interestingly, the propensity for urinary infection persisted in the children born to bacilluric women, whereas none of the children born to healthy controls demonstrated urinary infection.

Further evidence supporting a lifelong risk for symptomatic urinary infection in individuals presenting during childhood is reported by the Goteborg Childhood UTI Research Group. These authors followed 111 women with renal scarring or recurrent UTIs. Febrile UTIs were more prevalent than nonfebrile UTIs during the first 10 years of life but continued to occur into the third decade. Although the prevalence of febrile UTIs diminished in adulthood, women with renal scarring during childhood were significantly more likely to have subsequent febrile UTIs. Overall, the median incidence of symptomatic UTIs was 7 per individual.[21,22]

Bacteriology

The organisms that colonize the urinary tract are specifically adapted towards this purpose. Research has identified specific virulence factors that determine an organism's pathogenic potential, thus differentiating strains commonly associated with asymptomatic bacteriuria, cystitis, or acute pyelonephritis. However, uropathogenic strains do not rigorously conform to predicted behavior. Rather, a few general principles are applicable, such as the presence of surface molecules important for adhesion and toxins that assist tissue invasion.

A large family of Gram-negative, aerobic bacilli known as Enterobacteriaciae cause the majority of uncomplicated UTIs. Included in this family are the genera *Escherichia*, *Klebsiella*, *Enterobacter*, *Citrobacter*, *Proteus*, *Providencia*, *Morganella*, *Serratia*, and *Salmonella*. Of these, *E. coli* is by far the most frequently isolated organism, being responsible for approximately 80% of UTIs. This family of bacteria is generally characterized by a negative reaction to the oxidase test and the capacity to ferment glucose and reduce nitrates to nitrite. *Pseudomonas* is also a Gram-negative, aerobic bacillus but is distinct and unrelated to Enterobacteriaciae. Most *Pseudomonas* recovered from the urine are of relatively low virulence and do not tend to invade tissue unless host defense mechanisms are compromised.

The most common Gram-positive organisms found in UTIs are *Staphylococcus* and *Enterococcus*. Anaerobic fecal flora rarely produce UTIs despite being 100 to 1000 times more abundant than *E. coli* in stool.[23] Occasionally, unusual or fastidious organisms may produce infections that are difficult to detect because they do not grow well in commonly used culture media. For example, *Haemophilus influenzae* has been reported to cause urinary infections,[24] as well as epididymo-orchitis in infant males.[25] Other unusual organisms include *Salmonella* sp. and *Shigella*. Although lactobacilli, corynebacteria, and alpha streptococcus may rarely cause UTI, they probably should be considered contaminants unless they are found in culture of specimens obtained by suprapubic aspiration or by catheterization.

The bacteriologic findings in the Goteburg study suggest that 'the [predisposing] environmental conditions in the periurethral region and the host defense mechanisms vary with age and sex'.[11] This study identified four characteristic bacteriologic trends in childhood urinary tract infections:

1. A high frequency of *Proteus* sp. infections in older boys (most of whom were uncircumcised), and greater variability in infecting organisms in boys than in girls.
2. A greater likelihood of staphylococcal infection in adolescence, especially in girls.
3. A greater frequency of *E. coli* urinary infection in neonatal boys than in girls of that age.
4. A decreased frequency of *Klebsiella* urinary infection in older children (Table 7.3)

Other general rules include the fact that the majority of uncomplicated infections are caused by a single organism. Patients with complicated infections, particularly those children who have been managed with long-term catheterization, may have multiple organisms. Sometimes the strain of bacterium is suggestive of underlying urinary pathology, such as the relationship of *Proteus* sp. and struvite stones.

Serology

E. coli, the most common species of uropathogens, can be typed serologically by three major groups of antigenic structures capable of producing specific antibodies. There are more than 150 O (cell wall)

Table 7.3 Infecting bacteria (%) isolated from 'first-time' urinary infection in children categorized by age and gender

	Females (%)			*Males[a] (%)*	
Infecting organism	All neonates (n = 73)	1 month to 10 years[b] (n = 30)	10–16 years (n = 30)	1 month to 10 years (n = 62)	10–16 years (n = 42)
E. coli	**57% (females) 83% (males)**	**83%**	**60%**	**85%**	**33%**

antigens, more than 50 H (flagellar) antigens, and approximately 100 K (capsular) antigens. Not all strains are typable. Serologic classification in UTI is restricted mainly to O antigens. Early studies have attempted to correlate serologic markers with increased virulence or tissue invasiveness. Most of these were epidemiologic studies that were conducted prior to discovery of the special role of specific virulence factors, such as adhesins (attachment structures). In contrast to patients with cystitis or asymptomatic bacteriuria, patients with pyelonephritis have been found to be more frequently infected with certain O typable strains and strains having certain K antigens. Eight O antigen types (O1, O2, O4, O6, O7, O18, O25, O75) were the cause of 80% of cases of pyelonephritis in one report.[26] Another study reported that *E. coli* possessing five K antigens (K1, K2, K3, K12, K13) accounted for 70% of isolates from patients with pyelonephritis.[27] These serologic studies have been extended to identify more specific O:K:H combination serotypes characteristic of pyelonephritogenic strains.

Virulence factors

The term virulence simply refers to the ability of microorganisms to cause disease. The concept of uropathogenic bacteria refers to certain strains that are selected from the fecal flora, not by chance or prevalence, but because of the presence of specific virulence factors that enhance colonization of the uroepithelium. Other virulence factors aid in persistence of bacteria in the urinary tract and provide these organisms with the capacity to induce inflammation of the urethra, bladder, or renal parenchyma. Recognized *E. coli* virulence factors include but are not limited to (1) adherence to uroepithelial cells, (2) elaboration of endotoxin, (3) ability to evade phagocytosis, (4) ability to damage host cells and other bacteria, (5) ability to acquire iron, and (6) resistance to serum bactericidal activity. Studies of pyelonephritogenic strains of *E. coli* reveal the presence of a limited number of bacterial clones that possess specific virulence factors that are expressed only in certain O groups.[28] In a mouse model of acute pyelonephritis, it was determined that each virulence factor has a role causing UTI. Although the presence of P-fimbriae and hemolysin was significantly associated with mortality, additional factors functioned synergistically to augment a strain's pathogenicity.[29]

Adherence

Bacterial adherence or attachment is an essential initiating step in all infections. Perineal colonization by uropathogenic bacteria has been found to precede clinical UTI in women and children at risk for UTI.[6,30–33] Tissue invasion, inflammation, and cell damage are secondary events. Uropathogenic bacteria, especially *E. coli*, can attach to specific receptor sites (bacterial tropism) by means of specialized proteins (adhesins) on the ends of attachment structures (fimbria). Non-specific adherence also occurs by electrostatic and hydrophobic forces. In addition to recognizing constituents of uroepithelial cell surface, fimbriae also attach to constituents of the basement membrane. By virtue of such attachment, virulent strains of bacteria can ascend into the upper urinary

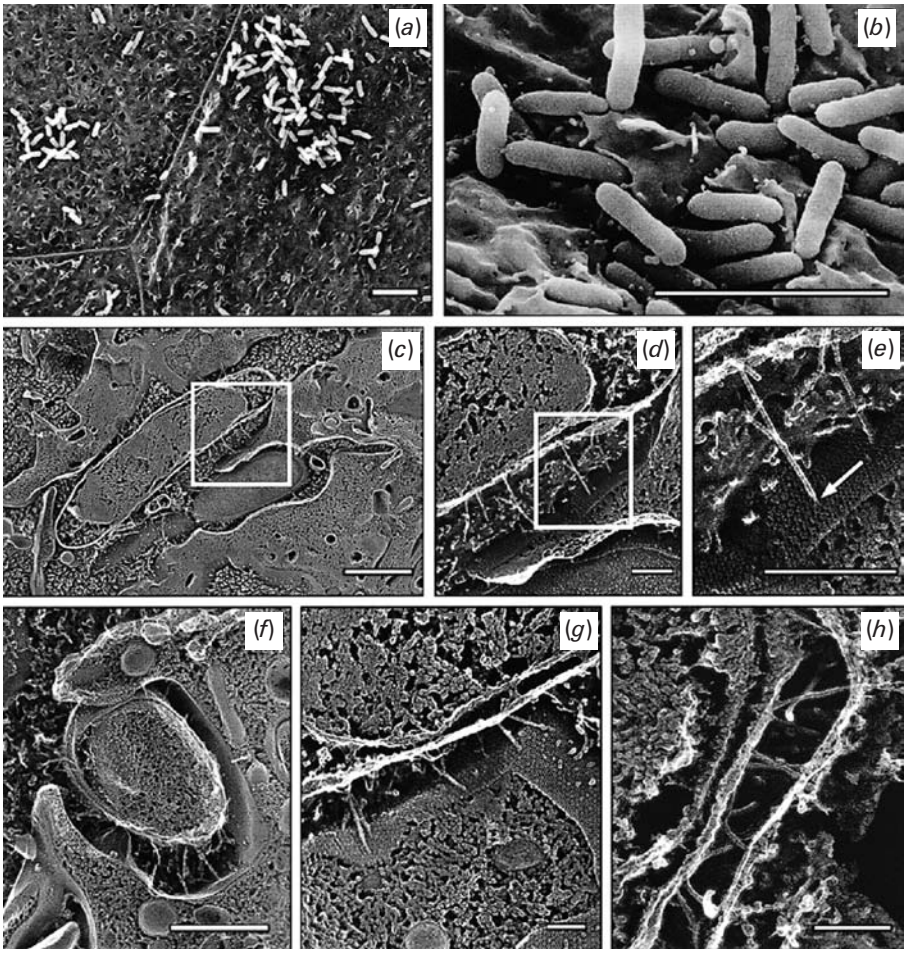

Figure 7.2 Type 1 pilus-mediated bacterial adherence to the bladder epithelium. The boxed areas in (*c*) and (*d*) are shown magnified in (*d*) and (*e*), respectively. The arrow in (*e*) indicates the FimH-containing tip. In (*h*), type 1 pili span from the host cell membrane on the right to the bacterium on the left. Scale bars = 5 μm (*a, b*), 0.5 μm (*c, f*), and 0.1 μm (*d–h*). (From Malvey et al.[34])

tract even in the absence of structural abnormalities such as vesicoureteral reflux (VUR).

Several different types of fimbriae have been identified. Type 1 fimbriae mediate agglutination between bacteria and cells in culture. Type 1 fimbriae bind specifically to mannose-terminated glycoproteins on uroepithelial cell surfaces. Since this agglutination can be competitively inhibited by a mannose-rich solution, type 1 fimbriae are often termed mannose-sensitive. Alternatively, P-fimbriae recognize a glycolipid commonly found on uroepithelial cells of the upper urinary tract through a mannose-resistant interaction (Figure 7.2). Uropathogenic bacteria rely on both mannose-sensitive type 1 fimbriae and mannose-resistant P-fimbriae to colonize the urinary tract. The expression of type 1 and P-fimbriae varies between 'on' and 'off' states, and is likely regulated by environmental conditions.[35] In addition to type 1 and P-fimbriae, uropathogenic bacteria employ several other adhesins, both fimbrial and non-fimbrial. Unfortunately, little epidemiologic evidence exists that clarifies the role of these additional adhesins on *E. coli* (S-fimbriae, FIC-fimbriae, S/FIC-related fimbriae), *Klebsiella* (MR/K HA), and *Proteus* sp. (MR/P HA, PMF, ATF, NAF, UCA) in the pathogenesis of UTI.

In addition to promoting attachment, type 1 fimbriae mediate bacterial invasion into the uroepithelial cells themselves, thus protecting bacteria from antibiotics that do not penetrate the cell's membrane, such as aminoglycosides.[34] In fact, viable internalized bacteria can be isolated from uroepithelial cells 48 hours after infection, and may account for recurrent infection by the same bacterial strain (Figure 7.3). Once type 1 fimbriated *E. coli* attach, the uroepithelial cells

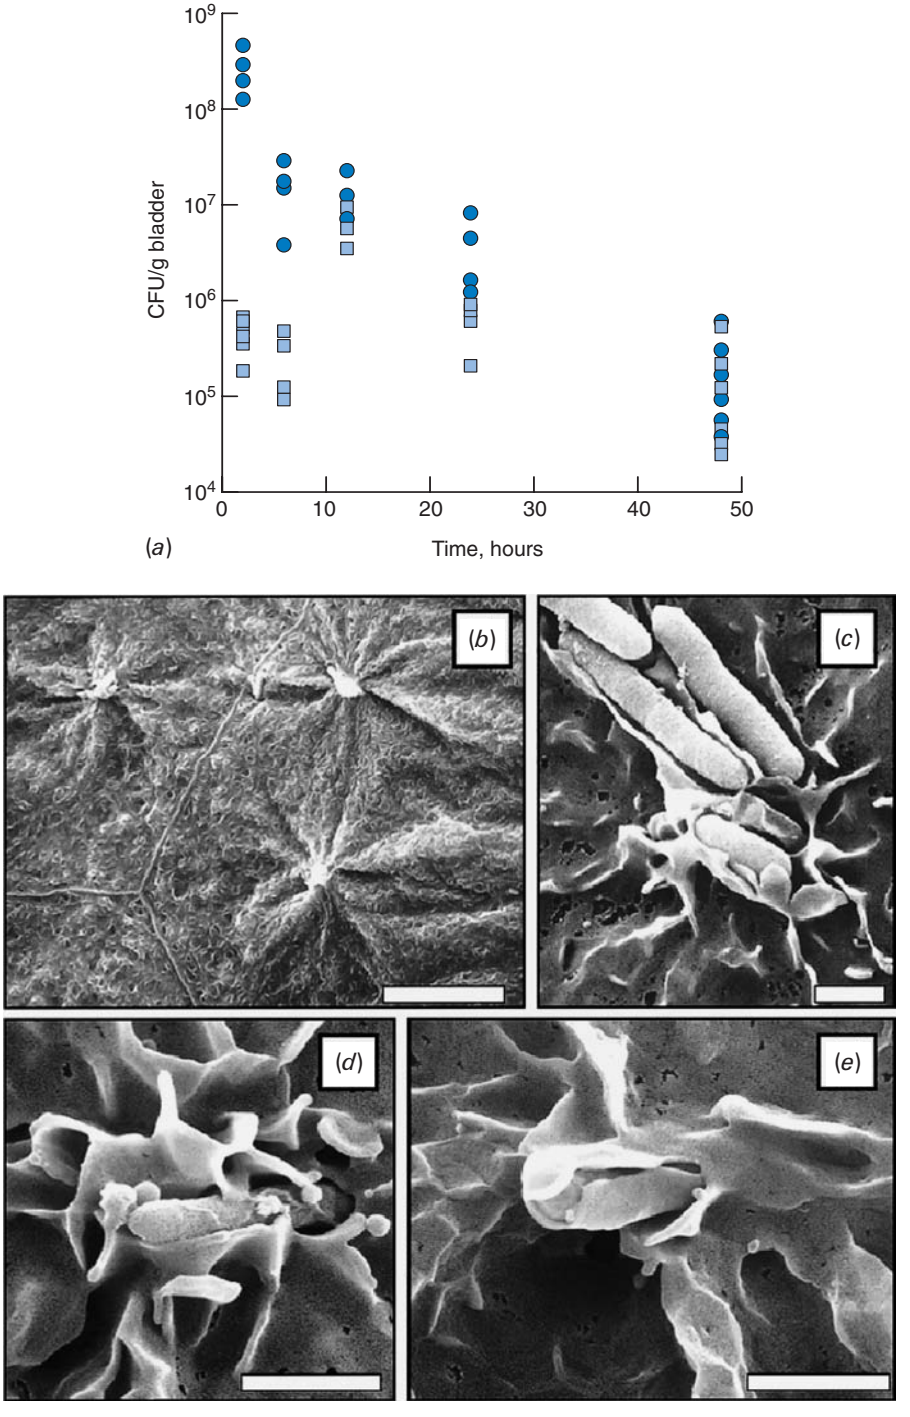

Figure 7.3 Kinetics of bacterial reduction in *E. coli* NU14-infected bladders and the persistence of intracellular bacteria. (*a*) The total numbers of bacteria per gram of mouse bladder (circles) and the numbers of gentamicin-protected bacteria (boxes) were examined per time point. (*b–e*) Bacteria in various stages of internalization into superficial cells at 2 h after infection with *E. coli* NU14 were detected by scanning electron microscopy (SEM). Scale bars = 10 μm (*b*) and 1 μm (*c–e*). (From Malvey et al.[34])

undergo apoptosis (programmed cell death) that results in bladder mucosal ulceration.

Although the entire urothelial surface, including the upper urinary tract, contains glycoprotein receptors for type 1 fimbriae, no evidence exists that implicates type 1 fimbriae directly in the pathogenesis of pyelonephritis. However, it has been demonstrated in experimental models and clinical studies that once

pyelonephritis occurs, the presence of type 1 fimbriae significantly increases a strain's ability to persist in the urinary tract and to stimulate inflammation.[36–39]

Clinical and experimental studies have shown that pyelonephritic *E. coli* frequently possess fimbriae that can recognize and agglutinate erythrocytes of the P-1 blood group. Hence, this type of pili have been termed P-fimbriae. The P-fimbriae attach to the carbohydrate portion (α-D-galactopyranosyl-(1–4)-β-D-galactopyranoside) of the glycolipid antigen in the P blood group series, which is also expressed by human uroepithelial cells.[40,41] The components of P-fimbriae are encoded by 11 genes in the pyelonephritis-associated pilus (pap) gene cluster, of which pap E, F, and G, encode for the adhesin subunits.

Further research has identified that not all P-fimbriae are alike. Proteins located at the tip (G-tip proteins or tip adhesins) determine the fimbria's specific attachment properties. Three classes have been identified, of which only class II and class III P-fimbriae have uropathogenic potential. In-vitro studies have found that the class III P-fimbriae bind receptors found in higher density on bladder uroepithelium. In contrast, class II tip adhesins may be more important in the evolution of acute pyelonephritis by virtue of an increased density of class II specific receptors located on the uroepithelium of the upper urinary tract.[42] James-Ellison et al have described a statistically significant greater likelihood of clinical and histologic indicators of acute pyelonephritis in primates inoculated with class II fimbriated *E. coli* than when primates are inoculated with class III fimbriated *E. coli*.[43]

Epidemiologic studies in children have provided considerable evidence that the presence of P-fimbriae on *E. coli* is a significant virulence factor, particularly in upper urinary tract infections. These studies have shown that 76–94% of pyelonephritogenic strains of *E. coli* are P-fimbriated compared with 19–23% of cystitis strains, 14–18% of strains isolated from patients with asymptomatic bacteriuria, and 7–16% of fecal isolate strains.[28,44] Other evidence supporting the importance of P-fimbriae in causing upper urinary tract infections comes from animal model studies. Inoculation of the bladders of non-refluxing primates with P-fimbriated *E. coli* resulted in pyelonephritis in 66% of animals. In contrast, pyelonephritis was not seen in any of the monkeys inoculated with non-P-fimbriated *E. coli*.[45]

In addition to their role in the pathogenesis of pyelonephritis through attachment to renal epithelial cells, P-fimbriae also function to promote intestinal carriage by the host, as well as enhancing perineal colonization (see host factors) and persistence in the urinary tract. Although the data regarding intestinal carriage and perineal colonization (see host factors) by P-fimbriated *E. coli* strongly implicate the P-fimbriae in the pathogenesis of infection, the data regarding bacterial persistence are less clear.

Although fimbriae appear to be the primary method by which bacteria colonize the urinary tract, there is also attachment to non-exposed 'receptors' located in the interstitium. Secondary binding to fibronectin occurs by means of fimbriae encoded by pap, papG, sfa, afa and prsG DNA sequences; a feature also more common in pyelonephritogenic strains than in strains causing cystitis or asymptomatic bacteriuria.[46,47] Other adhesins may actually play a protective role by preventing UTI through competitive binding. For example, S-fimbriae and type 1 fimbriae bind to Tamm–Horsfall protein and low molecular weight substances, respectively. Once bound, clearance of bacteria by periodic shedding of these soluble bacteria–protein complexes in the urine offers a theoretical advantage by reducing the number of infecting organisms.

Some data suggest that an organism's phenotype is variable, first facilitating colonization of the uroepithelium, then undergoing specific changes (phase variation) to evade eradication by the host's immune response, as well as promote ascent within the urinary tract.[48] *E. coli* alternately express type 1 then P-fimbriae as UTI progresses from colonization to cystitis, then to pyelonephritis. Some type 1 bacteria do reach the renal parenchyma (as in the case of VUR). These bacteria, however, must then escape type 1 fimbria-specific neutrophil receptors. In-vitro studies have demonstrated that neutrophils elicit a more severe inflammatory response in the presence of type 1 fimbriated strains than when in the presence of a mutant strain lacking the type 1 fimbria.[37] Phase variation to non-type 1 fimbriated strains is known to occur, thereby conferring a potentially protective advantage. Despite this apparently unified view of bacterial virulence, several studies also exist to challenge any attempt to simplify the complex interaction between bacteria and host.[49,50] In fact, the appearance of P-fimbriated strains in the periurethral region of girls at risk for cystitis does not inevitably result in urinary infection.[51] Thus, bacterial virulence properties should not be the sole focus of blame in the development of UTI. Host risk factors probably are of equal, if not greater, significance.

Despite its significance, bacterial adherence is only one of several factors believed to have a role in infection. Other bacterial virulence factors and host

defense factors may play an even greater role in tissue invasion and inflammation. In an experimental study in mice, the presence of P-fimbriae was necessary for colonization of the upper urinary tract but did not produce tissue invasion unless combined with other virulence factors.[52] Similarly, in a clinical study that employed dimercaptosuccinic acid (DMSA) renal scans to document acute parenchymal inflammation in children with febrile UTI, no difference in the prevalence of P-fimbriated *E. coli* was found in children with an abnormal scan compared with those who had a normal scan.[53] Likewise, renal scarring has been reported to be more common following pyelonephritis caused by non-*E. coli* organisms when compared to those caused by P-fimbriated *E. coli*.[42,54]

Other virulence factors

1 Endotoxin. A lipopolysaccharide present in the bacterium's cell wall, endotoxin, is responsible for initiating the acute inflammatory response common to Gram-negative infections.
2 K antigen. Capsular polysaccharides afford K antigen specificity to *E. coli*. K antigen has been shown to shield bacteria from complement lysis and phagocytosis and to enhance persistence of bacteria in the kidneys of experimental mice.[55–59] It is more commonly isolated from children with clinical pyelonephritis than in those from children with cystitis or healthy controls.[57–60]
3 Hemolysins. Cytotoxic proteins, such as hemolysins, are another recognized virulence property capable of damaging renal tubular cells, in vitro. Hemolytic strains of *E. coli* produce more severe experimental pyelonephritis in mice.[61]
4 Colicin: Another protein elaborated by pyelonephritogenic *E. coli,* colicin kills other bacteria in the vicinity of the *E. coli* producing it. The colicin V plasmid is also thought to encode for an iron uptake system that further promotes the survival and pathogenicity of colicin-producing organisms.[62]
5 Iron-binding capacity: Most bacteria require iron for optimal growth and metabolism and have developed mechanisms to acquire iron when there is limited supply. Mediated by such proteins as aerobactin, iron-binding capacity has also been shown to be associated with increased virulence in epidemiologic studies.[63,64]
6 Serum resistance: In the presence of fresh human serum, many strains of *E. coli* are killed following activation of complement. Serum resistance to such killing action is another property that has been related to virulence of Gram-negative bacteria both in UTIs and Gram-negative bacteria.[65,66]

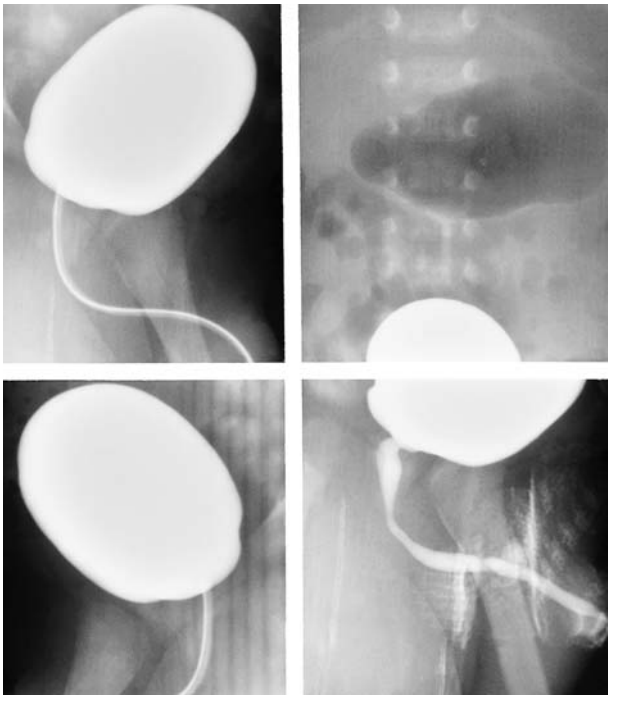

Figure 7.4 Voiding cystourethrogram demonstrating the absence of vesicoureteral reflux and obstructive pathology (posterior urethral valves, ureterocele) in an uncircumcised infant boy with acute pyelonephritis confirmed by ^{99m}Tc DMSA renal scan.

Although these virulence factors have been considered separately, their effect appears to be additive. In contrast to those with cystitis or asymptomatic bacteriuria, the majority of bacterial isolates in patients with non-reflux acute pyelonephritis express three or four virulence properties.[42] Interestingly, the frequency of P-fimbriae and other virulence factors is significantly lower in patients who have VUR (Figures 7.4 and 7.5). This would appear logical since, in the presence of reflux, virulence properties such as adherence are not necessary for bacteria to reach the upper urinary tract. It has been suggested that efforts aimed at interfering with 'virulent' bacteria, such as by vaccination, may be of less value in patients with recurrent pyelonephritis and reflux, the group in whom renal scars are more likely to develop. However, others have not demonstrated a significant difference in virulence traits among pyelonephritogenic strains in patients with and without reflux.[67]

Role of bacterial virulence in renal scarring

Regardless of their role in the etiology of urinary tract infection, some studies suggest that there may be a

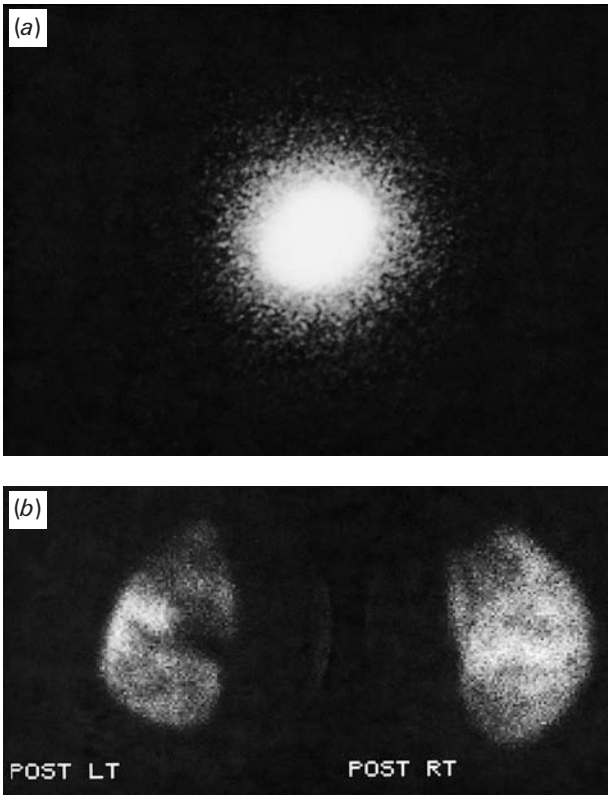

Figure 7.5 (*a*) Isocystogram demonstrating the absence of vesicoureteral reflux in a child with (*b*) ^{99m}Tc DMSA renal scan documented acute pyelonephritis (upper and lower poles are affected).

paradoxical relationship between bacterial virulence, defined by P-fimbriated binding, and renal scarring. In one study of patients with recurrent pyelonephritis, virulent clones expressing P-fimbriae occurred significantly less often in those who developed scarring (22%) than in those who did not develop renal scars (62%).[42] Although the frequency of scarring among girls with VUR was 57% in contrast to 8% of those without reflux, this alone did not explain the selection of bacteria of low virulence in those patients with scar development. Lomberg et al[42] concluded that reduced host resistance was essential for the tendency to renal scarring after acute pyelonephritis (APN).

In rodent models of APN, type 1 fimbrae have been implicated in the pathogenesis of renal scarring by virtue of stimulating neutrophil chemotaxis, the oxidative burst necessary to generate reactive oxygen species, and the release of lysosomal proteins from neutrophils.[68–70] Other evidence suggests that more virulent bacteria, as measured by the presence of adhesins, may elicit a more rigorous inflammatory response than less virulent clones and are thus cleared more rapidly. An alternative explanation would be that children infected with more virulent bacteria present earlier with symptoms such as fever, resulting in more prompt diagnosis and treatment. Observations in patients with bladder dysfunction and asymptomatic bacteriuria have demonstrated a low prevalence of P-fimbriated *E. coli* (less than 20%), suggesting that the presence of specific attachment structures may not be necessary for bacterial persistence in the urinary tract.[56,71,72] Moreover, coincident with an inflammatory response, P- and type-1 fimbriated *E. coli* were demonstrated to be more rapidly cleared than non-fimbriated strains from individuals with bladder abnormalities.[73]

Host defense factors

Interacting with bacterial virulence properties are an equally important and complex number of mechanical, hydrodynamic, anti-adherence, receptor-dependent, and immunologic host factors that affect an individual's susceptibility to UTI. By necessity, these factors are closely interrelated to the pathogenesis of UTIs, beginning with the route of entry of bacteria into the urinary tract.

Perineum

Hematogenous seeding of the urinary tract is an uncommon source of urinary infection in children. When this is the cause of a renal infection, a cortical abscess rather than classic pyelonephritis is more likely to occur. Considerable clinical and experimental evidence has clearly established an ascending or retrograde urethral route of entry of bacteria in the majority of UTIs. The same bacterial strains causing urinary infections can be found on perineal cultures prior to bladder invasion. This is in contrast to negative perineal cultures in healthy controls.[74–77] The usual organisms originate from fecal flora that colonizes the perineum.[78]

An infant's initial exposure to uropathogenic bacteria occurs at the time of birth, subjecting infants born to bacilluric mothers to a fourfold greater risk of urinary tract infections.[79,80] It has been postulated that other host defense factors mature during the first year of life, resulting in a decrease of both periurethral colonization and frequency of UTI. Overall, the quantities and species of colonizing bacteria in the periurethral area diminish during the first year of life until few remain at age 5 years. Meanwhile, normal periurethral flora may even be protective against urinary infection by competitive interference with attachment of uropathogenic bacteria.[81,82] This

potential protective effect can be altered by the administration of antimicrobial agents, given for any reason. In a study of children with first-time acute pyelonephritis, significantly more children had been recently treated with antibiotics, usually for non-UTIs, compared with controls.[83] In general, the genitalia of infant boys are more heavily colonized than are those of infant girls, and, when colonized, boys carry *E. coli* more frequently than do girls. These data concur with Winburg's epidemiologic findings that UTI occurs less frequently with advancing age and more frequently in boys younger than 6 months than in their female counterparts.

Ultimately, an infant's own intestinal tract may become colonized by bacteria with uropathogenic potential. Wold et al[84] reported on 13 girls with asymptomatic bacteriuria who underwent characterization of fecal flora. Resident strains isolated from affected girls more commonly expressed P-fimbria, were adherent to colonic epithelium in a mannose-resistant fashion, and were one of several uropathogenic serotypes present when compared with transient strains of *E. coli*. Plos et al[85] confirmed these findings in a prospective review of fecal isolates from children with UTIs. Affected children demonstrated intestinal colonization with P-fimbriated *E. coli* more frequently than healthy controls both during infection (86% versus 29%) and during infection-free intervals (40% versus 29%).

Since Bollgren and Winburg's original work in 1976 in school-age girls with a history of recurrent UTIs,[86] three additional studies have reported on the natural history of periurethral colonization. Despite the widely accepted concept of an ascending route of infection, the mere presence of uropathogenic bacteria on the perineum did not portend symptomatic UTI. Schlager et al[51] studied the association between periurethral colonization and recurrent UTI in a cohort of seven toilet–trained girls (3–6 years of age). Each girl underwent weekly periurethral and urinary cultures during a 6-month period immediately following her first UTI. Almost half (43%, 53/122) of the periurethral cultures were positive; however a positive perineal culture was obtained equally as often in the absence of urinary infection as it was prior to a symptomatic recurrence. Moreover, in only one of the four recurrences was the causative organism isolated from a perineal culture. Similarly, although heavy periurethral colonization has been reported in 75–80% of healthy infants and toddlers of both sexes,[86] only 1–3% become infected.[11] In a study similar to Schlager's, Brumfitt et al[87] found that perineal colonization by the responsible organism did not precede the symptomatic recurrent UTI in up to 34% of the adult women studied. These data may reflect the transient nature of bacterial species colonizing the perineum. Alternatively, these findings may reflect the short time course between initiation of perineal colonization and symptomatic UTI by uropathogenic bacteria in certain individuals.

Although it is not unreasonable to suspect that an abrupt change in the expression of certain key virulence factors might precipitate ascent from the perineum to the bladder, some data exist to refute this hypothesis. Schlager et al[51] characterized the expression of six virulence factors among *E. coli* colonizing the bladder in the absence of symptoms and those causing symptomatic UTI in seven girls. Although P-fimbriae were commonly identified in infecting species of *E. coli*, none of the six virulence factors, including P-fimbriae, accurately predicted which colonizing species would ultimately cause symptomatic infection. Thus, although sufficient evidence exists to support bacterial ascent into the bladder from the perineum as the mode of entry, the facilitating events in that mechanism remain poorly understood.

Prepuce

A hematogenous route of infection, rather than ascent into the urinary tract from the perineum, has been suggested in the newborn. This proposal was based on the more frequent finding of bacteremia associated with UTI in this age group.[6] However, others have not substantiated a higher incidence of bacteremia in neonates compared with other infants and children with febrile UTIs.[3,18] Furthermore, the increased risk for UTI (including pyelonephritis) in uncircumcised boys compared with both girls and circumcised boys provides additional convincing support for an ascending route of infection even during the first several months of life. In fact, over 90% of boys with febrile UTIs during the first year of life are uncircumcised.[6,88] In 1985, Wiswell et al[10] initially found a 20-fold higher rate of UTI among infant boys who were not circumcised than among those who were (4.12% vs 0.21%). Subsequently, two larger cohort studies by the same investigator, encompassing 637 097 infants, found the rate of UTI among uncircumcised boys to be less than that originally described, but still significantly greater (10-fold) than the incidence of UTI among those circumcised[88,89] (Table 7.4). Rushton and Majd[88] prospectively found that 92% of boys under 6 months of age hospitalized with febrile UTIs were uncircumcised compared with 49% of a control

Table 7.4 Incidence of urinary tract infection (UTI) in female and circumcised and uncircumcised male infants (0–1 year old) born in US army hospitals (1974–83)

	Total No.	No. with UTI	Rate per 1000
All males	217 116	661	3.0
Circumcised	175 317	193	1.1
Uncircumcised	41 799	468	11.2
Females	205 212	1164	5.7

Modified from Wiswell and Roscelli.[91]

group of infant boys hospitalized with febrile respiratory infections.

Evidence exists to implicate the prepuce as a reservoir for uropathogenic bacteria. Wijesina et al prospectively cultured the periurethral flora before and after circumcision in 25 boys. Prior to circumcision 52% (13/25) of the boys were colonized by potentially uropathogenic organisms as opposed to none of the boys after circumcision. Other studies have demonstrated that uropathogenic P-fimbriated *E. coli* adhere well to the mucosal surface of the prepuce, whereas non-pathogenic *E. coli* do not.[30,88,90]

One must wonder what differs in neonatal boys recognizing that the incidence of pyelonephritis declines throughout childhood despite the persistence of foreskin and periurethral colonization. In a retrospective study, Kim suggested that the increased risk of UTI in neonates might be related to the inability to retract the foreskin.[92] However, many boys cannot retract their prepuces until adolescence. Despite this conflicting evidence, the periurethral area of the uncircumcised infant is a closed space, harboring bacteria with the potential to cause serious urinary infection in some boys.[30,93] Consequently, circumcision may help to prevent UTI in male infants by removal of the mucosal surface necessary for bacterial adherence to occur. However, since even in uncircumcised boys the incidence of UTI is low, the debate regarding routine circumcision as a preventive health measure will likely continue. Justification for circumcision in boys who have other risk factors for UTI such as antenatally detected hydronephrosis associated with posterior urethral valves, megaureters, or high-grade VUR, is more easily argued.

Urethra

The short urethra in girls appears to be the most obvious explanation for the increased relative incidence of UTIs in girls as compared with boys after the first 6–12 months of life. Narrowed urethral caliber, historically blamed as the pre-eminent factor influencing susceptibility to lower UTIs in girls, does not play a role. It has long been established that the intrinsic urethral luminal size is not significantly narrower in those girls who are bacteriuric compared with those who never have been infected.[94,95] In fact, both of these studies demonstrated that the urethral diameter was slightly larger in infected groups than in those never infected. Consequently, there is no role for urethral dilation or other cystoscopic procedures in the routine management of childhood UTIs.

Other commonly held misconceptions related to the etiology of UTIs are that improper wiping techniques and bubble baths predispose to urinary infections. There is no evidence to support these myths. The strongest evidence against improper wiping techniques being a cause of UTIs is that over 95% of non-toilet-trained infants never develop urinary infection despite daily exposure to soiled diapers. Although bubble baths may occasionally cause dysuria from local meatal or vaginal irritation, there is no association with bacterial cystitis. More important for urethral ascent into the bladder is the ability of uropathogenic bacteria to attach to uroepithelial cells. Similar to the findings with periurethral cells,[96] increased adherence of bacteria to uroepithelial cells has been demonstrated in children prone to urinary infections.[97] This implies a difference in host receptor density or affinity that influences an individual's susceptibility to infection.

Dysfunctional elimination

One of the most important host risk factors for recurrent UTIs is voiding dysfunction. Common voiding disorders in children prone to UTI range from the small-capacity, unstable bladder characterized by frequency, urgency, posturing, and wetting to the infrequent voider ('lazy bladder syndrome') characterized by very infrequent voiding, a large-capacity bladder, paradoxical incontinence (wet despite a large bladder capacity), and constipation. The prevalence of some of these is listed in Table 7.5.[98] Numerous reports have linked dysfunctional voiding and recurrent UTIs in children.[99–105] Attention has also been focused on the association between dysfunctional voiding and the presence of VUR in infants and children with recurrent UTIs.[103,106,107] Chen and coworkers performed a multivariate logistic analysis to identify the association between VUR, UTI, and dysfunctional elimination in 2759 girls and boys. Dysfunctional

Table 7.5 Prevalence of symptoms characteristic of dysfunctional elimination in 7–8 year-old schoolchildren: results of Danish Epidemiological Questionnaire Survey

	Girls (%)	Boys (%)
Urge symptoms	20	21
Day wetting	13	9
Night wetting	13	22
Nocturia	7	6
Encopresis	5	8
Emptying difficulties	8	7

From Hansen et al.[98]

elimination was present in 36% of the girls and 20% of the boys with VUR. UTI was not associated with dysfunctional elimination in children without VUR; however, those with VUR and UTI had a twofold greater risk of dysfunctional elimination.[107] The predisposition to recurrent UTIs and VUR in children with dysfunctional voiding is related to the presence of residual volume resulting from inadequate emptying of the bladder, increased intravesical pressure created by uninhibited bladder contractions, and bladder overdistention from infrequent voiding habits.[108] The elimination of bacteria from the bladder by frequent and complete emptying plays a significant role in preventing infection.[109] In a group of girls followed with asymptomatic bacteriuria (ABU), the incidence of recurrent bacteriuria correlated directly to bladder emptying. The average postvoid residual urine volume in those with ABU was 23.7 ml, whereas in normal controls it was 1.1 ml. On follow-up, recurrent bacteriuria was present in 75% of those with more than 5 ml of postvoid residual urine as compared with only 17% of those with less than 5 ml of residual urine.[26] The establishment of normal voiding habits in these children has been shown to reduce the incidence of recurrent UTIs.[110–112]

Paramount to identifying the dysfunctional voider is a thorough voiding history. Squatting, delayed or infrequent micturition, urgency, constipation and/or encopresis are significant symptoms which frequently can be elicited in 50–90% of children with urinary tract infection.[102,104,113–118] Hellstrom et al[18] reported an abnormal voiding history in up to 49% of girls presenting between 3 and 5 years of age with their first urinary tract infection. Specifically, the presence of daytime urinary symptoms strongly correlated with the risk for subsequent infection. In a related study of the same children, Hansson[100] found that a majority of girls with 'covert' bacteriuria had urodynamic evidence of dysfunctional bladders when compared with controls. Wan et al[119] evaluated the relationship between toileting habits and anatomic abnormalities that predispose to infection in 101 children with UTI (77 girls and 24 boys). Ninety percent of the children without structural abnormalities demonstrated dysfunctional elimination as a contributing factor to their urinary infections, compared with 40% of those patients found to have a structural abnormality such as VUR.

Similarly, there is a definite correlation between constipation and urinary incontinence, VUR, and recurrent UTIs in children.[120,121] Constipation classically is characterized by infrequent bowel movements that are large caliber and firm. This may be associated with perineal and/or abdominal pain from colonic distention. Paradoxically, children with constipation may be referred for encopresis (fecal soiling), a manifestation of the elimination of loose stool around feces impacted within the rectal vault. Unfortunately, physical examination of the constipated child is unreliable and often a soft abdomen or empty rectal vault is encountered even when significant constipation is present radiographically. Likewise, the diagnosis of constipation can be difficult in children under 5 years who are unable to provide an accurate history.

A growing body of evidence suggests that constipation is an important facet of disordered elimination that, if appropriately managed, can help reduce the number of recurrent UTIs and promote resolution of VUR. Although this theoretically may be the result of mechanical factors related to compression of the bladder and bladder neck by a hard mass of stool, it is more likely due to the frequent coexistence of constipation with dysfunctional voiding and incomplete bladder emptying. In an epidemiologic questionnaire surveying 1597 Danish children 7–8 years old (863 girls, 728 boys, 6 gender unknown) the overall prevalence of encopresis was 13.9% (5.6% girls, 8.3% boys)[98] (Table 7.6). Among the girl respondents, 75 had a history of UTI and 13% of these suffered from encopresis vs only 6% of the girls without UTIs. Moreover, in a prospective study of 234 chronically constipated children, approximately one-third of the children demonstrated associated daytime incontinence (24%) and nighttime incontinence (34%), which reflects the degree to which bowel and bladder elimination disorders are interrelated.[111] The resolution of constipation resulted in disappearance of day- and nighttime incontinence in a majority of children (89% and 63%, respectively). Most significant was

Table 7.6 Difference in micturition symptoms in girls with and without prior urinary tract infection (UTI)

Symptoms	Prior UTI (n = 75) (%)	No history of UTI (n = 723) (%)	p-Value

Table 7.7 Prevalence of elimination symptoms among 143 children with primary vesicoureteral reflux (VUR)

Symptom	Prevalence (%)
Constipation	23
Bladder instability	19
Infrequent voiding	16

From Koff et al.[122]

the impact on the frequency of UTIs (approximately 10% of total), that completely disappeared in children without structural abnormalities.

Chronic constipation also plays a role in the etiology of recurrent UTIs in children with primary VUR. Recently, Koff et al[122] have demonstrated that up to 50% of the children with VUR who might otherwise be considered 'normal' have significant disorders of elimination (Table 7.7). Of the dysfunctional elimination symptoms, chronic constipation was the most prevalent in the presence of recurrent UTIs.[122] Many children without a history of UTI had detrusor instability in the absence of infection. Of those studied who had VUR, dysfunctional elimination significantly increased the risk of breakthrough UTIs, resulting in more frequent reimplantation surgery in these children. Additionally, it took 1.5 years longer for primary VUR to resolve in children with dysfunctional elimination (constipation included) compared with those without any elimination symptoms, despite a lower mean grade of reflux in those with dysfunctional elimination.

Immunologic factors

Heredity

Evidence that heredity plays a role in determining individual susceptibility to UTI is accumulating. The daughters of mothers who had been bacteriuric in childhood show a higher incidence of UTI, and female siblings tend also to show a higher incidence of bacteriuria.[20,123] Children with first-time pyelonephritis significantly more often have relatives with a history of UTI than do controls.[83] Racially dependent differences in the prevalence of UTIs and in the rate of bacteriuria have also been reported. Kunin[12] reported a 1.2% bacteriuria prevalence rate in white girls vs a rate of 0.5% in black girls in the same age group. In a retrospective review, the number of black girls evaluated following UTI who were found to have VUR was one-third that of white girls at an institution where equal numbers of black and white girls were hospitalized.[124] This observation was subsequently confirmed by a prospective study of patients admitted to this same institution with febrile UTIs.[7] Experimental urinary tract infection in mice is also significantly influenced by heredity, as evidenced by a slower response to treatment in certain strains of inbred mice as compared to others in which the UTI resolves more rapidly.[125] These same studies have also demonstrated that the acute inflammation and acquired immune response (antibody production) that follows urinary infection differs among genetically different strains of mice. As stated, '[this] result strongly suggests that the presence or absence of specific host genes will determine how effectively an *E. coli* UTI will be resolved.'

Table 7.8 Distribution of antigens in secretions and on epithelial cells and erythrocytes in the secretor and non-secretor phenotype

	Secretor	Non-secretor
Secretions (saliva, mucus)	ABH antigens	No ABH antigens
Epithelial cell	Le^{b+}, Le^{y+}	Le^{a+}, Le^{x+}
Erythrocytes	Le^{a-}, Le^{b+}	Le^{a+}, Le^{b-}
	Le^{a-}, Le^{b-}	Le^{a-}, Le^{b-}

Subsequent work has determined that innate immunity is the critical effector of inflammation and reparative processes that influence the resolution of UTI. Most of the research in this field has focused on genetic determinants within this cascade that influence the risk of acquired renal cortical scarring. Specifically, polymorphisms within the angiotensin-converting enzyme gene (ACE I/D) and tumor necrosis factor-alpha (TNF-α G308A) gene have been strongly associated with acquired renal scarring, whereas genetic abnormalities of cytokines and transforming growth factor-beta (TGF-β) have been less strongly correlated.[126–130]

Antiadherence

Epidemiologic and in-vitro data support the hypothesis that some blood group antigens behave as bacterial receptors in addition to their long-recognized role in determining red cell phenotypes. Of the many carbohydrate antigens, the role of ABH, Lewis antigens (Le^a, Le^b, Le^x, and Le^h), P, Kell, Duffy, MNS, and Kidd systems in host susceptibility to urinary infection is becoming better understood. Blood group antigens can be found on the surfaces of many epithelial cells in the body, including vaginal and uroepithelial cells, and as secreted antigens in mucus in addition to on erythrocytes.[131] Presumably, bacterial colonization of epithelial surfaces is facilitated by cell-surface-bound antigens, whereas secreted antigens mitigate against colonization by virtue of competitive inhibition.

Individuals belong to one of two distinct phenotypes based on the expression of ABH and Lewis antigens on cell surfaces and in secretions (Table 7.8). The secretor phenotype is characterized by ABH antigens in saliva, Le^b and Le^y antigens on epithelial cell surfaces, and Le(a^- b^+) erythrocytes. Non-secretors have mucus devoid of ABH antigens, express Le^a and Le^x antigens on epithelial cells, and have Le(a^+ b^-) erythrocytes. Those with Le(a^- b^-) erythrocytes can be secretors or non-secretors, depending on the presence of ABH antigens in secretions.

Since bacterial attachment to glycoprotein (type 1 fimbriae) or glycolipid (P-fimbriae) receptors are critical steps in colonization and tissue invasion, respectively, an individual's risk for UTI may be influenced by the composition of surface receptors available for bacterial attachment. Observations by Schaeffer and coworkers in healthy women found that the profile of antigen expression on vaginal cells and in vaginal mucus correlated with the ABO phenotype and secretor status.[132] They also noted that individuals within the same blood group phenotype expressed different amounts of ABH and Lewis antigens. Moreover, longitudinal analysis demonstrated that the level of expression of these antigens fluctuated over time.[133] However, utilizing quantitative immunohistochemical techniques, Schaeffer's group did not identify an association between a particular phenotype and a positive history of UTI when controlling for secretor status.[134] Thus, despite the appealing hypothesis that some individuals may be more susceptible to bacterial colonization by virtue of genetically determined cell-surface antigens, these data do not support this notion in adult women.

In children, similar associations between blood group phenotypes and the risk of UTI have been sought. Sheinfeld et al[135] studied the expression pattern of blood group antigens in 72 tissue specimens from children who underwent urologic surgery for anatomic abnormalities of the urinary tract. Sixty-six percent (48/72) had a history of UTI and the remainder served as controls. Although an increased susceptibility to UTI was noted among non-secretors as compared with secretors, the high risk of UTI was most likely a consequence of the prevalence of structural abnormalities in this study population.[135] Jantausch et al[136] performed a more extensive analysis of blood group antigens in seven different systems and found that only the Le(a^-b^-) phenotype correlated with a positive history of febrile UTIs in children, yielding a threefold relative risk. Recently, Albarus et al[137] sought to confirm the association between blood

group phenotypes and the susceptibility to childhood febrile UTIs. In a well-matched case–control study of children with a febrile UTI during the first year of life, no such association existed. If blood group phenotypes and secretor status do not influence the risk of UTI, as some data might suggest, then perhaps the susceptibility to UTI is mediated by urinary or epithelial factors that are as yet unidentified.

Urinary inhibitors

Although urine commonly provides the appropriate environmental conditions for successful bacterial growth, several constituents within urine have been identified that inhibit bacterial growth. Normally, the pH of urine fluctuates between 4.6 and 7.2 in accordance with physiologic needs. Since the optimal pH range for bacterial growth is between 6 and 7, increases in urine acidity can limit bacterial growth. Extremes of urine osmolarity can also inhibit bacterial growth by virtue of the limited nutrients available to support replication in dilute urine (hypo-osmolarity) or of the dehydration that ensues in concentrated urine (hyperosmolarity). Tamm–Horsfall protein, a glycoprotein secreted by luminal cells of the ascending loop of Henle, may also be protective. This glycoprotein has been shown to contain abundant mannose residues and is identical to uromucoid. In-vitro studies have shown adherence of large numbers of *E. coli* with type 1 fimbria to uroepithelial cells coated with uromucoid in contrast to poor adherence to uroepithelial cells devoid of uromucoid.[138] It has been postulated that free Tamm–Horsfall protein in the urine may trap *E. coli* possessing type 1 fimbriae, thereby inhibiting attachment to uroepithelium. In fact, two studies have demonstrated such binding between type 1 and S-fimbriae and Tamm–Horsfall protein.[139,140] Tamm–Horsfall protein has also been demonstrated to bind to neutrophils, and it is believed that this interaction mediates recognition of bacterial invasion by neutrophils.[141] A study of UTIs in infants revealed a significantly lower mean concentration of Tamm–Horsfall protein in those with documented *E. coli* infections compared with healthy controls.[142]

Receptors

Bacterial adherence, particularly by P-fimbriae on certain strains of *E. coli*, appears to be particularly significant in the pathogenesis of upper urinary tract infections. As discussed earlier, a special class of glycosphingolipids, possessing Gal 1–4 Gal oligosaccharide, act as receptors for P-fimbriated *E. coli*.[40,41] These receptors are antigens in the P blood group system. It is felt that host susceptibility to bacterial adherence is conferred by the P1 blood group phenotype, since this group is over-represented in children with recurrent pyelonephritis in contrast to normal controls.[143,144] However, this over-representation of the P1 blood group phenotype is seen only in patients with pyelonephritis who do not have associated VUR.[143] Despite the tenuous association between non-secretor status and an increased susceptibility to UTI, apparently as a result of diminished secretion of antiadherence factors, a recent study has identified the presence of specific attachment structures for *E. coli* in non-secretors. Stapleton et al[145] have identified glycosphingolipids on vaginal and renal epithelial cells that bind each of the three major classes of *E. coli* adhesins. Of the glycosphingolipids studies, sialosyl galactosyl globoside was determined to be the preferred binding receptor for uropathogenic *E. coli*. Bergsten et al[146] have shown that bacterial attachment through P-fimbriae is sufficient to activate the innate host response. Thus, an individual's risk for UTI may be more strongly influenced by the presence of receptors for bacterial attachment, rather than the absence of blocking antigens.

Immunity

The immunologic response to UTI has been studied at both the kidney and bladder level. Understanding the immune response to infection is particularly important because immunization is currently being explored as a possible means of preventing recurrent UTIs. The antibody response to infection has also been used diagnostically to localize the level of urinary infection to the upper or lower urinary tract.[147,148]

Antibody response

The focus of most of the clinical and experimental immunologic studies of UTI has been the immune response to pyelonephritis. During acute pyelonephritis a systemic antibody response occurs with antibody production primarily against the O antigen of the infecting bacteria. A diminshed response is seen toward the K antigen.[61,149] Counteracting bacterial adherence to host epithelial cells are protective antibodies that may be passively acquired (from mother to fetus) or actively acquired through previous exposure to infection. Conversely, in the absence of protective antibodies some individuals are

at greater risk for UTI.[150] Antibodies of the immunoglobulin M (IgM), IgG, IgA, and secretory IgA (sIgA) type have all been demonstrated in the serum and urine of children and experimental animals with acute pyelonephritis.[151,152] High IgG, IgA, and secretory IgA antibody levels have also been found in the urine of girls with pyelonephritis.[152] The presence of antibodies within the renal parenchyma enhances bacterial opsonization, the process by which bacteria are coated by proteins, which leads to further phagocytosis.

Antibody response to pili has also been found following pyelonephritis.[153] Secretory IgA directed against pili has been recovered from the urine of patients with acute pyelonephritis and has been shown to prevent in-vitro adherence of *E. coli* to human uroepithelial cells.[154]

Mannose-specific interactions between *E. coli* and the carbohydrate moiety of secretory IgA have been reported.[155] Secretory IgA, when bound to the uroepithelium, may thus offer a receptor site for bacteria. When excreted, it may result in competitive inhibition of binding.

With regard to the immune response of the bladder to urinary infection, a systemic circulating antibody response to cystitis is not seen.[152,156] However, an elevation of secretory IgA antibody in the urine has been observed in children with UTI, suggesting local antibody production.[152,157] A more recent study reported a decreased excretion rate of secretory IgA in uninfected children with a history of symptomatic infections compared with healthy controls. However, when these girls were subsequently studied at the time of symptomatic UTI, secretory IgA excretion rates were significantly higher than in controls.[158] Other evidence supporting a role for secretory IgA as a host defense factor comes from animal studies. Attempts at local immunization of the urinary tract have shown that intravesical immunization is effective against experimentally induced ascending UTI in rats.[159] The presence of secretory IgA in the urine following local bladder or vaginal immunization has been shown to decrease adherence to uroepithelial cells in this experimental model.[160,161]

The urine of newborns has nearly undetectable levels of sIgA that increase during the first year of life, particularly in breastfed as compared with non-breastfed infants. Case-control studies have identified a diminished incidence of UTI in breastfed infants, presumably related to soluble substances that are absorbed enterically and excreted into the urine. Using high-performance liquid chromatography to purify oligosaccharides in breast milk, Coppa et al[162] identified small molecular weight, neutral oligosaccharides that significantly decreased adhesion between human uroepithelial cells and *E. coli* isolated from an infant with UTI. Additionally, breast milk contains T and B lymphocytes, cytokines, growth factors and, most importantly, antibodies that may act synergistically to decrease the breastfed infant's risk of UTI.

No differences have been noted in the levels of urinary sIgA among boys and girls, and thus impaired immunity does not explain the higher incidence of UTI in infant boys as compared to girls. Instead, the predominance of UTI in infant boys likely reflects local periurethral factors (especially among uncircumcised boys).[43]

Cell-mediated immunity

The protective role, if any, of cell-mediated immunity in UTI is controversial.[163] T and B lymphocytic response is seen in the kidney during experimental pyelonephritis.[164] However, others have shown a depressed cell-mediated response during the early phase of renal infection when bacterial replication is maximal.[165] Although such studies have documented cell-mediated host responsiveness to bacterial infection, they have not defined the role of this process in the pathogenesis of UTI. There is no strong clinical evidence to support abnormality of cell-mediated immunity in patients prone to UTI. Experimental UTI in mice has demonstrated no increased susceptibility to *E. coli* in athymic animals (with dysfunctional cellular immune systems) and normal controls.[166] Similarly, in patients with compromised immune systems, an increased susceptibility to UTIs has not been reported. Studies to better define the role of cell-mediated immunity in UTI are obviously needed.

Innate immunity

Normally, uroepithelial cells have the capacity to produce cytokines when exposed to bacteria in vivo and in cell culture systems. Whereas these molecules serve as chemoattractants for inflammatory cells, they also participate in the uroepithelial cells' own response to invasion by pathogenic bacteria (see Table 7.3). The specific stimulus for uroepithelial cell cytokine production and release appears to be components of P- and type-1 fimbriae, since urinary levels of interleukin-6 (IL-6) are significantly greater in the presence of adhering bacteria and adhesin positive P-fimbriae.[161–169] Further in-vitro studies have determined that in response to direct contact between bac-

terial fimbriae and receptors located on the uroepithelial cell membrane, the uroepithelial cell is able to suppress bacterial growth.[170] These receptors have subsequently been identified as the 'toll-like receptor', an evolutionarily old system of pathogen recognition that is homologous to the interleukin-1 receptor. Moreover, utilizing human uroepithelial cells in culture, Mannhardt and coworkers[170] have demonstrated that, in individuals with a history of recurrent UTIs, a transmembrane defect impedes signal transduction within the urothelial cell, thus rendering the cell incapable of responding to bacterial attachment. Among the 10 identified toll-like receptors, TLR-2 and -4 are the most relevant to the investigation of APN since these recognize antigens present on the surface of uropathogenic bacteria: peptidoglycans and lipoproteins (TLR-2) and lipopolysaccharide (TLR-4). TLR-2 and -4 participate with other membrane-bound proteins to stimulate transcription of cytokine genes, including TGF-β, which has been implicated in tissue fibrosis.[171] In mice, disruption of the downstream effects of TLR-2 and -4 stimulation results in delayed bacterial clearance and renal cortical scarring.[172] These data lend support to the concept that the most important arm of cellular immunity in the urinary tract may not be T and B cells, as classically described, but instead the inherent ability of the uroepithelium to respond to bacterial invasion.

Vaccines

Much of the significance of clarifying the immune response to UTI relates to the possibility of developing an effective vaccine to prevent urinary infections. Experimental evidence has accumulated to suggest that this may be possible in the near future. Protection against experimental ascending pyelonephritis in rats has been demonstrated using isolated capsular antigen to stimulate antibody production directed at K antigen.[159] Similarly, immunization with *E. coli* P-fimbriae in both mice and primates confers protection against ascending pyelonephritis, presumably by interfering with adherence of the organism to the uroepithelium.[173–175] Immunization of rats with purified type-1 fimbriae also affords substantial protection against experimental ascending pyelonephritis.[176] Thankavel et al have identified the specific subunit region within the FimH determinant of type-1 fimbriae that is responsible for attachment to uroepithelial cells. Antibodies directed specifically against this region of only 25 amino acids, and not other regions on FimH or FimA subunits of type 1 fimbriae, reduced experimental pyelonephritis in mice.[177] Some evidence suggests a potential role for immunization with hemolysins as well.[52]

Recent clinical investigations have demonstrated the efficacy of acquired immunity as prophylaxis against recurrent UTIs in women and children. Both vaginal and intramuscular immunization with inactivated uropathogenic bacteria has resulted in significantly increased levels of sIgA.[178] In a small trial involving only 10 girls with recurrent UTIs and an equal number of healthy controls, intramuscular immunization also resulted in significantly fewer recurrences in the girls vaccinated.[179] Although these results are promising, the full value of such vaccines to prevent pyelonephritis will be critically assessed only by appropriately controlled, large clinical trials.

Anatomical abnormalitites of the upper urinary tract

Vesicoureteral reflux

Numerous reports have documented that vesicoureteral reflux is present in 25–50% (average 35%) of children with culture documented UTIs.[180] In contrast, in a survey of the literature Bailey reported an incidence of VUR in children without UTI of only 0.4–1.8%.[181] Similar findings were reported by Ransley, who compiled voiding cystograms in 535 children without a history of UTI and found VUR in only 7 children (1.3%).[182] Vesicoureteral reflux, when present, continues to be the most significant host risk factor in the etiology of childhood pyelonephritis. The risk for both acute pyelonephritis and subsequent renal scarring is directly related to the severity of VUR. In one prospective study of children with febrile UTIs, approximately 80% of patients with VUR demonstrated changes consistent with acute pyelonephritis on technetium-99m (^{99m}Tc) DMSA renal scans, including 100% of patients with moderate to severe reflux (grades III–V/V).[53] In contrast, only 60% of patients without demonstrable reflux had evidence of acute pyelonephritis on the DMSA scan. Kidneys associated with moderate or severe reflux were twice as likely to demonstrate abnormalities on DMSA scans (67%) when compared with kidneys with mild (32%) or no reflux (34%). In a compilation of 10 published clinical studies of children with febrile UTIs, DMSA renal scan abnormalities have been reported in 50–80% of children.[183] When VUR was present, approximately 80–90% of patients had abnormal studies, including almost all with moderate or severe VUR.

The presence of VUR appears to compensate for decreased virulence of *E. coli* in patients with recurrent pyelonephritis.[42] When there is reflux of infected urine from the bladder into the upper urinary tract, bacteria do not require special virulence properties, such as cellular attaching ability, to ascend from the bladder to the kidney. In one study of girls with recurrent pyelonephritis, infections were caused by P-fimbriated *E. coli* in only 36% of those with VUR compared with 71% of those without VUR.[42] Despite the important role that VUR plays when it is present, studies of children with febrile UTIs have reported that the majority of patients (60–68%) with abnormal DMSA renal scans demonstrating acute pyelonephritic changes do not have demonstrable VUR at the time of investigation.[183]

In children with dysfunctional voiding, the presence of residual urine and elevated voiding pressures during urinary tract infection is more likely to result in significant post-pyelonephritic renal scarring than anticipated for the grade of VUR present. Perhaps because of more frequent breakthrough infections while on antibacterial prophylaxis, these children have been found to be at greater risk for progressive renal scarring (up to 44%).[184]

Obstruction

Urinary obstruction may occur at the ureteropelvic junction, the ureterovesical junction, or the posterior urethra in boys with valves. Patients with obstruction may present with severe infection. Ectopic ureters, with or without associated ureteroceles, also represent obstructed pathology. However, such anomalies are present in only a minority of children with UTIs. In fact, recent prospective studies of children presenting with first-time febrile UTIs have reported significant obstructive uropathy in fewer than 1%.[185] Perhaps this lower incidence is due in part to the increased detection of hydronephrosis on prenatal ultrasonography prior to the development of clinical infection. The increased predisposition to infection presumably results from impairment of urinary flow with resultant stasis that compromises bladder and renal defense mechanisms. Both obstruction and high-grade reflux result in an increase in the residual volume of urine in the bladder or dilated urinary tract, permitting the multiplication of bacteria in the urine.[109] Obstruction also inhibits the mechanical washout or flushing effect associated with ureteral peristalsis and effective micturition and may alter other local defense factors as well. All of these factors result in increased susceptibility of the parenchyma to infection and damage.

Diagnosis of urinary tract infection

Urinary tract infection can be reliably diagnosed only by urine culture. Symptoms of dysuria, urgency, frequency, and enuresis are non-specific and may be the result of vulvitis, urethritis, dysfunctional voiding, or non-specific causes, such as dehydration associated with febrile illness. In 34 children with lower urinary symptoms alone, urine culture demonstrated significant bacteriuria in only 18%; 40% of those with sterile urine had upper respiratory tract infection.[186] Similarly, Heale et al[187] found that of 378 children with specific urinary complaints, only 14.3% had urinary infection. Thirty-three percent with flank pain, frequency, and/or dysuria and 31.5% with the recent onset of wetting had UTI, whereas only 4.2% with chronic nocturnal enuresis were infected. Of those without specific complaints, 4.4% had UTI (there was little difference from those who were wet only at night).

Urinalysis

Although routine urinalysis can be helpful in calling attention to those who might be infected, the association of inflammatory cells in the urine by itself is at best only about 70% reliable.[6,188,189] The finding of significant pyuria on routine urinalysis varies with the volume of urine centrifuged and examined, the force and duration of centrifugation, the volume in which cells are resuspended, and observer error.[190] Urine microscopy for bacteria significantly improves the reliability of urinalysis for the detection of urinary infection, particularly when one combines this with examination of urinary sediment for pyuria.[191] Jenkins et al reviewed approximately 40 publications reporting urine microscopy for bacteria and found a wide variation in methodology and diagnostic criteria. They concluded that the least reliable method was examination of unstained, uncentrifuged urine. When stained, centrifuged urine was examined, the sensitivity using the criteria of one or more organisms per oil immersion field was greater than 95% when compared with urine culture growing ($\geq 10^5$ colony-forming units (CFUs) per ml. The specificity was at least 95% when more than 5 organisms per oil immersion field were viewed. Hoberman et al have compared quantitative urine cultures with an 'enhanced' urinalysis for the detection of pyuria and bacteriuria in urine specimens obtained by catheterization in children presenting with fever. The

data obtained demonstrated that UTI is best defined by more than 10 leukocytes/mm^3 on urinalysis combined with urine cultures yielding more than 50 000 CFU/ml.[192] In contrast, dipstick determination for the presence of leukocyte esterase and nitrite yielded sensitivities of only 52.9% and 31.4%, respectively, in detecting clinically significant bacteriuria (greater than 50 000 CFU/ml). In both this and another study of febrile infants, the findings of urinalysis were compared with the results of ^{99m}Tc (DMSA) renal scans. Both studies concluded that acute pyelonephritis in febrile infants is almost always associated with the finding of pyuria on urinalysis.[192,193]

Partly as a result of the technique and operator-dependent variability with urine microscopy, a number of enzymatic methods for detection of bacteriuria or pyuria have been developed. The two most popular are the leukocyte esterase and the nitrite reductase tests. These studies are inexpensive, rapid, and easy to perform.

Leukocyte esterase test

The leukocyte esterase dipstick test demonstrates the presence of pyuria by histochemical methods that specifically detect esterases in the neutrophils. When compared with chamber count methods, studies have reported sensitivity as high as 88–95% for the detection of pyuria using a cutoff of 10 or more leukocytes/mm^2.[32,194] However, in a study which evaluated 110 children with fever and positive urine cultures, the leukocyte esterase test had sensitivities of only 52.9% and 66.7% in detecting ≥10 and ≥20 leukocytes/mm^3, respectively.[189] Furthermore, one would not anticipate this test to be any more sensitive than the finding of pyuria alone for the identification of children with positive urine cultures.

Nitrite test

Bacteria convert urine nitrate to nitrite. The nitrite method employs reagent paper impregnated with sulfanilic acid and α-naphthylamine that form a red azo dye when in contact with nitrite. Thus, a positive colorimetric assay implies the presence of bacteria in the bladder. However, a relatively long incubation period (4 hours) is required for conversion of nitrate to nitrite. For this reason, first morning urine sample in a toilet-trained child is the best specimen to test. A single test on a randomly collected urine specimen was reported to have a sensitivity of only 29.2–44% on 790 urine specimens using dipsticks from two manufacturers. However, the specificity was 98% when the test was positive.[194,195] This test is not a reliable office screening method when used alone.[194]

Combining the leukocyte test and the nitrite test on a single dipstick has improved the accuracy to detect or exclude UTI. In a review of rapid methods to detect UTIs, Pezzlo reported a sensitivity of 78–92% and a specificity of 60–98% when using the combination test.[196] However, the accuracy is affected by the probability of the patient being infected based on clinical findings.[196,197] Accordingly, urine culture may be omitted when the dipstick test is negative only when there is limited suspicion for UTI based on clinical symptoms. Conversely, urine culture should be obtained in any patient suspected of having a UTI or in whom the dipstick test is positive.

Others have evaluated the role of urinary *N*-acetyl-β-glucosaminidase (NAG) (a renal tubular enzyme thought to be a marker of tubular damage), β_2-microglobulin (β_2M) (a low molecular weight circulating protein with increased fractional excretion in children with tubulointerstitial disease) and IL-8 in the diagnosis of pyelonephritis in febrile children. Unfortunately, NAG and β_2M have been found in both children with febrile UTIs and in children with sterile urine who had severe renal scarring associated with high-grade VUR. Elevated IL-8 urinary levels are also non-specific, as they have been seen in inflammatory disorders other than acute pyelonephritis. Thus, these markers are currently unreliable for the diagnosis of acute pyelonephritis.[135,198–200]

Urine culture

In the pre-toilet-trained group, the urine specimen is often obtained by applying a collection bag. The results of a bag urine specimen are reliable *only* when the specimen is negative. Contamination is directly related to the length of time the bag is in place. If a specimen has not been obtained within 30 minutes of application, reliability begins to decrease. Removing the appliance and plating or refrigerating the urine immediately after the child voids is paramount. Having the parent apply the bag before leaving for the physician's office in an effort to shorten the wait is acceptable only when the cultured specimen is negative. When confirmation of voided urine or immediate treatment is necessary, bladder catheterization or suprapubic aspiration (SPA) should be employed. A feeding tube (8–10 Fr) inserted only a few centimeters into the bladder is ideal for catheterization. In girls and boys who can void on command, midstream specimens are more reliable than bag-collected specimens.

SPA has achieved popularity in some centers. Young children are particularly favorable candidates for SPA because of the abdominal location of their urinary bladders. However, the procedure cannot be expected to be successful when the bladder is empty. This is the major drawback of SPA. If urine is not obtained initially, time should not be wasted in a sick child who requires antibiotic treatment. Urethral catheterization should be done. SPA is performed after first cleaning the suprapubic area with an antiseptic solution. A 21–25 gauge needle is inserted perpendicular to the patient in the midline, one finger-breadth above the symphysis. Although a local anesthetic can first be infiltrated, this appears unnecessary and may actually cause more pain than a quick in-and-out aspiration. It is practical to apply a U-bag to the perineum prior to cleansing the abdomen. Many times the child voids during preparation for aspiration, obviating the necessity for the procedure if the voided urine is immediately plated or refrigerated.

It has often been stated that 'any number of bacteria' obtained by SPA are significant. Since the bladder is a reservoir and this method of collection depicts the number of bacteria in that reservoir, one should not anticipate colony counts significantly different from those properly collected by other means. Ginsburg and McCraken found ≥100 000 CFU/ml in 96% and 40 000–80 000 in the remaining 4% of 100 febrile infants with bacteriuria demonstrated on SPA.[6] None showed fewer than 40 000 colonies. Nelson and Peters had previously reported similar results in a study of premature and term infants.[201] Hoberman et al recently reported the results of positive urine cultures on specimens obtained by catheterization in 110 febrile infants <2 years old.[192] Of 110 urine cultures with ≥10 000 CFU/ml, 92 (84%) had ≥100 000 CFU/ml, 10 (9%) had 50 000–99 000 CFU/ml, and only 8 (7%) had 10 000–49 000 CFU/ml. Furthermore, urine specimens with 10 000–49 000 were much more likely to yield Gram-positive or mixed organisms than specimens with >50 000 CFU/ml. These authors concluded that UTI is best defined by ≥10 leukocytes/mm^3 and colony counts of ≥50 000 on catheterized specimens. Thus, colony counts from the bladder <50 000 CFU/ml are suspect regardless of the manner in which the urine was collected.

Clinical presentation and localization

As one would anticipate, the classic signs and symptoms for UTI are usually lacking in the very young.

Table 7.9 Prominent symptoms in neonatal non-obstructive urinary tract infection: combined results of four studies (n = 255)

Symptom	Prevalence (%)
Failure to thrive or weight loss	51
Fever	41
Jaundice	12
Cyanosis/pallor	30
Vomiting	35
Diarrhea	29
Convulsions/CNS symptoms	20

Instead, non-specific symptoms – such as irritability, poor feeding, failure to gain weight, vomiting, and diarrhea – may be the only signs suggestive of an underlying problem (Table 7.9). In one study of children with symptomatic urinary infections, only 9% of 78 infants were initially referred with a suspected diagnosis of UTI.[202] Often absent in neonates, fever is present in most infants between 1 and 12 months old who present with symptomatic UTIs.[5,11,19] In fact, urinary tract infections have recently been described as one of the most common serious bacterial illnesses among febrile infants and young children, with a reported prevalence ranging from 4.1% to 7.5%.[192] In one study of 945 infants who presented to a pediatric ER with fever, the overall prevalence of UTI was 5.3%.[203] The prevalence was highest in Caucasian girls, 17% of whom had a positive urine culture. In contrast, the prevalence of UTI among African-American girls was only 3.5% and among boys it was 2.5%. Another prospective study reported UTI in 7.5% of 442 infants (less than 8 weeks of age) presenting to the emergency room with fever ≥100.6°F (38.1°C), only half of whom had abnormal urinalyses suggestive of UTI (>5 white blood cells per high-power field or any bacteria present).[204] Thus, a urine specimen for culture, preferably collected by catheterization, should be obtained routinely whenever a non-verbal, non-toilet-trained child presents with unexplained fever.

As the child becomes verbal and is toilet-trained, urinary tract symptomatology is more easily detected. Fever continues to be relatively common in toddlers with first-time symptomatic infection. However, fever is not as frequently associated with recurrent and/or long-standing infection. In older children urgency, frequency, enuresis, and dysuria are common presenting symptoms. Failure to become toilet-trained at the proper age may occasionally

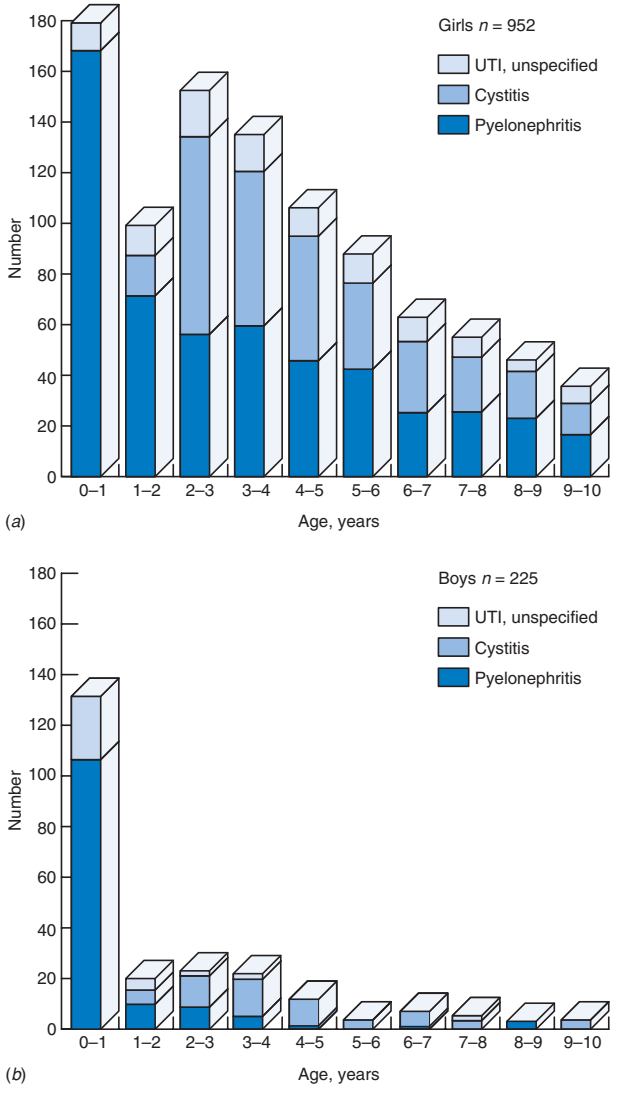

Figure 7.6 Children with first-time diagnosis of urinary tract infection at the Children's Hospital in Goteborg, Sweden, according to age and clinical diagnosis. (Reprinted from Jodal[206], with permission.)

herald underlying chronic lower urinary infection. Although urinary tract symptoms such as vaginal pain, urinary frequency, dysuria, and enuresis are common following childhood sexual abuse, actual urinary infection is not.[205]

There are few population-based studies of symptomatic UTIs in childhood. The classic epidemiologic study by Winberg et al[11] was carried out between 1960 and 1966 in Goteborg, Sweden. The special organizational structure of that city's pediatric medical care has afforded unique opportunities to perform ongoing epidemiologic studies of UTIs in children. Jodal[5] reported a follow-up prospective epidemiologic study conducted in Goteborg from 1970 to 1979. There were 952 females and 225 males (4.2:1) below age 10 years of age who were treated for a first-time symptomatic urinary infection (Figure 7.6).[206] Of the 225 boys, 59% presented during the first year of life. The number of boys diagnosed in the higher age groups was low, especially over age 5. The number of first infections in girls was also highest in the first year of life (19%). A gradual decrease in number of girls with first-time infections was associated with increasing age. In both girls and boys, febrile infections, presumed to be pyelonephritis, predominated during the first year of life. Acute cystitis was most commonly seen between 2 and 5 years of age in both sexes, with a marked peak frequency in girls during the third year of life. As expected, infections during infancy were the most difficult to characterize as pyelonephritis or cystitis.

Asymptomatic bacteriuria

The natural history and uroradiographic findings in patients with asymptomatic or covert bacteriuria vary according to the age of the patient and prior episodes of symptomatic infections. Screening bacteriuria does not necessarily represent asymptomatic bacteriuria, as approximately one-third of school-aged girls with screening bacteriuria have a prior history of symptoms related to the urinary tract and some have had previous symptomatic UTIs. It is unclear whether the prognosis is any different for children who have primary asymptomatic bacteriuria compared with those in whom asymptomatic bacteriuria develops following treatment of a symptomatic infection.

A study of asymptomatic and symptomatic bacteriuria in infants under 1 year of age reveals interesting differences in the two populations.[5] In 2 of 50 patients with asymptomatic bacteriuria, clinical acute pyelonephritis developed within 2 weeks of detection. The others remained free of symptoms. 46 (92%) of the patients with asymptomatic bacteriuria were evaluated with voiding cystourethrography (VCUG) and mild reflux (grades I to II) was found in only 5 (11%). Of 45 left untreated, 36 spontaneously cleared the bacteriuria and 8 others became abacteriuric following antibiotic treatment for other reasons. Although asymptomatic recurrences developed in 6 (12%), no pyelonephritic recurrences occurred in this group during follow-up of at least 1 year. Follow-up urography, done in 36, did not reveal any evidence of renal scarring. In contrast, among 40 infants with symptomatic infections, 1 patient had a significant ureteropelvic junction obstruction and 14 of 39 (36%) had VUR, including 3 with grade III or

greater. Fourteen of 40 (35%) experienced recurrences, including 6 with acute pyelonephritis and 3 with cystitis, whereas asymptomatic bacteriuria was noted in 5 patients. It was concluded that infants with asymptomatic bacteriuria represent a low-risk group with a tendency to spontaneously become abacteriuric, usually within a few months.

Considerable variation in uroradiographic findings has been reported in school-aged children found to have bacteriuria on screening. These studies have reported VUR in 19–35% and renal scarring in 10–26%.[12,15,16,207] However, many of these children had a prior history of symptomatic UTIs and others undoubtedly had infections during infancy that were overlooked or misdiagnosed. Although, recurrent infections following treatment occur in up to 80%, the risk for development of acute pyelonephritis in a girl older than 4 years of age with untreated asymptomatic bacteriuria is small and seems to be associated with a change in bacterial strain, perhaps as a result of antibiotic treatment.[12,208] Follow-up by the Cardiff–Oxford Bacteriuria Study Group revealed that those schoolchildren who presented initially with a radiographically normal urinary tract remained normal in spite of persistent asymptomatic bacteriuria.[209] Only in those children who had previous renal scarring did new scars or progression of scarring develop, and all of these children had VUR. Other studies have shown that asymptomatic bacteriuria is associated with low-virulence bacterial strains lacking the ability to adhere and cause symptoms.[44,154,210] Furthermore, there is considerable evidence that these organisms may be commensal with the host and may even protect against infection by more virulent strains.[211]

Cystitis

Acute cystitis in children is rarely associated with significant long-term morbidity. Typical symptoms that accompany acute cystitis in toilet-trained children include dysuria, frequency, urgency, and/or secondary-onset enuresis. Fever and systemic complaints are generally not a feature of the clinical picture. As previously mentioned, however, these same irritative lower tract symptoms are often seen in the absence of bacterial cystitis, mandating that a specimen for urine culture be obtained prior to institution of therapy.

Although the recurrence rate of lower UTIs is high, most cases can be considered little more than a nuisance and recurrences tend to decrease or disappear by adolescence. However, it is worth noting that many children prone to recurrent lower UTIs have voiding dysfunction, particularly infrequent voiding. Typically, these children do not void for 1 or 2 hours after awakening in the morning and then may void only two or three times throughout the day. Consequently, bladder capacity is abnormally large and bladder emptying is often incomplete. Often these children also have chronic constipation, including encopresis in some. Other children with recurrent cystitis have underlying bladder instability associated with urinary frequency, urgency, urge incontinence, and posturing associated with a reduced functional bladder capacity. Girls with a history of UTI are significantly more likely to report a variety of chronic voiding disturbances as compared to girls without a history of UTI[18,201] (see Table 7.6). In some cases, recurrent UTIs may be a precipitating factor to the child's voiding disturbance. Conversely, primary bladder instability may itself contribute to an increased susceptibility to UTIs. In contrast to daytime voiding disorders, isolated bedwetting is rarely associated with a history of previous UTI.[18]

Approximately 10% of susceptible girls will have a recurrent infection shortly after completion of a course of antibiotic therapy. These children have chronic symptoms of bladder instability. Squatting or posturing in response to unstable bladder contractions is common in this group. Many have voiding dyssynergia associated with high voiding pressures and incomplete bladder emptying. Some also have chronic inflammatory changes of the bladder. Historically, endoscopic evaluation of these children often revealed multiple raised 'cysts' in the area of the bladder neck and trigone. Histologically, submucosal lymphoid follicles were present. Clinically, this entity has been termed cystitis cystica, although the histologic appearance suggests it would be more accurately referred to as cystitis follicularis. The presence of these follicles suggests an immunologic response to chronic infection.[212] It should be noted that treatment of these children is no longer predicated on the basis of these endoscopic findings: rather, treatment is determined by the recurrence rate of infection and the type of underlying voiding and bowel disorder.

Pyelonephritis

Pathophysiology of acute pyelonephritis

Acute pyelonephritis represents the most serious type of UTI in children. It is not only responsible for greater acute morbidity but it also has the potential for causing irreversible damage. Acute pyelonephritis

in older children typically presents with fever and flank pain or tenderness associated with pyuria and positive urine culture. In the majority of cases, laboratory evaluation reveals an elevated serum white blood cell (WBC) count, erythrocyte sedimentation rate (ESR), and/or C-reactive protein (CRP). However, when compared directly with localization studies such as DMSA renal scans, these clinical and laboratory parameters are associated with high false-positive and/or false-negative rates.[183] This is particularly true in neonates and young infants, an age group at greatest risk for renal scarring following pyelonephritis. Neonates in particular present with non-specific symptoms such as irritability, poor feeding, failure to thrive, vomiting, and diarrhea (Table 7.9). When one considers that approximately half of all children with febrile UTIs present during the first year of life, the importance of early and accurate diagnosis becomes obvious.

Experimental studies by Roberts and others have found that bacterial adherence to uroepithelium elicits an inflammatory cascade proportional to the virulence of the infecting organism. The same acute inflammatory response that is responsible for the eradication of bacteria is also responsible for the damage to renal tissue and subsequent renal scarring.[213] Through a series of experimental studies using the primate model, Roberts has developed a unified theory of the chain of events involved in the process that ultimately leads to renal scarring (Figure 7.7).[214] The initiating event is bacterial inoculation of the renal parenchyma that elicits both immune and inflammatory responses. Whereas the immune response can be stimulated by live or heat-killed bacteria, the acute inflammatory response occurs only following inoculation by live bacteria.[213] Since heat-killed bacteria do not cause renal scarring, it appears that it is the acute inflammatory response that is more important as a cause for the subsequent development of permanent renal damage. Potent cytokines induce chemotaxis of granulocytes and cellular- and humoral-mediated bacterial killing.

Studies have also reported that focal ischemia may be a consequence of acute pyelonephritis. Kaack et al have shown that granulocyte aggregation within capillaries leads to vascular occlusion. Renal ischemia is then evidenced by a transient rise in circulating renin levels.[215] Hill and Clark found evidence of marked cortical vasoconstriction in areas of acute inflammation in rabbits with acute renal infection, with inflammatory cells obstructing the peritubular capillaries.[216] Androulakakis et al found microvascular changes in acute pyelonephritis in pigs using microradiologic and stereomicroscopic techniques. Focal ischemia in areas involved by the acute inflammatory response was evidenced by compression of glomeruli, small peritubular capillaries, and vasa rectae, presumably from interstitial edema.[217] Using the microsphere technique, Majd and Rushton evaluated renal blood flow changes associated with acute pyelonephritis in the refluxing piglet model. Focal renal blood flow was decreased in sites of acute pyelonephritis identified by diminished uptake of DMSA and subsequently confirmed by histopathology. Uninvolved areas of the affected kidneys demonstrated normal blood flow comparable to that of the contralateral normal kidney.[218]

Since host-derived cytotoxins are central in the genesis of tissue suppuration, investigators have tried to understand and modify the inflammatory response. Granulocytes kill bacteria, releasing toxic enzymes (lysozymes) both within the granulocyte and into the lumen of renal tubules, which causes renal cell damage. The respiratory burst, a phenomenon universal to acute inflammatory responses, generates oxygen radicals (superoxides) that have classically been felt to mediate bacterial killing, as well as that of granulocytes and surrounding tubular cells.[219]

The role of reactive oxidants, inducible nitric oxide (iNOS), and tissue-destructive proteinases in the acute inflammatory response has only recently been elucidated. In an extensive review of the literature spanning 70 years, Weiss proposes that neutrophil-derived superoxide and oxygen radicals are merely highly reactive intermediates in the production of toxic chlorinated oxidants (e.g. hypochlorous acid and chloramines). If these chlorinated oxidants are the true mediators of tissue destruction, then inhibiting their generation should lessen tissue injury. In fact, in-vitro models have demonstrated that cellular destruction could be prevented in the presence of specific inhibitors of the H_2O_2–halide–myeloperoxidase system, effectively preventing HOCl (hypochlorous acid) generation.[220] Despite this compelling evidence, Weiss' 'enthusiasm' for HOCl as the sole agent in inflammation-mediated tissue destruction is tempered by the fact that living tissue perfused with HOCl solutions remains viable.[221] However, evidence suggests that the primary role for HOCl and chloramines is to neutralize circulating enzyme inhibitors that prevent the untimely digestion of host tissues by neutrophils. These oxidants do have mild direct cytotoxic effects. Thus, in the absence of significant inflammation, any enzymes released from neutrophilic lysosomes are

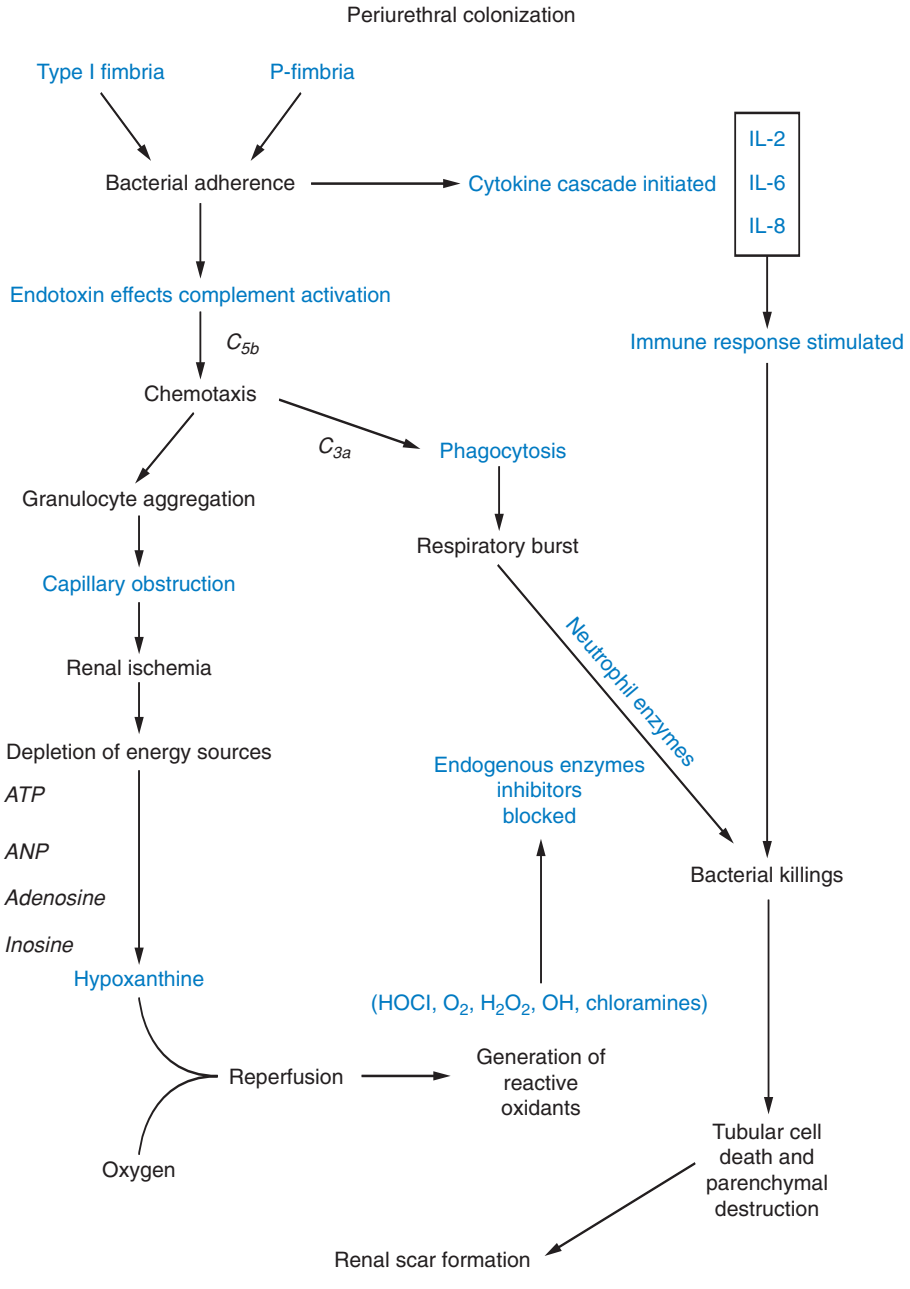

Figure 7.7 Diagram of the pathophysiologic events (from bacterial adherence to renal scar formation) that are characteristic of acute pyelonephritis. (Modified from Roberts.[214])

immediately inactivated. However, once stimulated, the neutrophil can release the aforementioned oxidants into its immediate surroundings and can create a microenvironment capable of inactivating enzyme inhibitors, activating latent neutrophil-derived enzymes, and rapidly degrading microbes, host cells, and connective substratum.[222] Tubular cell death releases the toxic inflammatory agents into the interstitium, causing further damage.

Oxygen radicals are also produced by cell reaction during reperfusion of ischemic tissue. Focal parenchymal ischemia, resulting from intravascular granulocyte aggregation and edema, occurs with bacterial infection of the renal parenchyma.[215,219,223] In ischemic tissue, hypoxanthine is produced during anaerobic metabolism of adenosine monophosphate. During reperfusion, hypoxanthine in the presence of xanthine oxidase and oxygen yields superoxides and hydrogen peroxide.[223] Treatment with allopurinol, an inhibitor of xanthine oxidase, protects against tissue damage from reperfusion injury and from that associated with bacteria in the renal parenchyma.[223]

It appears that the interstitial damage associated with the acute inflammatory response of pyelonephritis results from ischemia-related injury and from toxic enzymes. Additionally, bacterial virulence factors, such as hemolysins and lipopolysaccharides, work in concert with neutrophil-derived mediators to disrupt cellular membranes and degrade the extracellular matrix. The inflammatory process extends through the renal interstitium, thus contributing to the damage that ultimately results in irreversible renal scarring.

Recently, the impact of adjunctive corticosteroids on post-inflammatory renal scarring was evaluated in the treatment of experimental pyelonephritis in the refluxing piglet model. Following induction of acute pyelonephritis as confirmed by DMSA scintigraphy, animals were randomized to receive either standard antibiotic therapy or antibiotics and prednisolone (2 mg/kg daily). Two months later, DMSA scintigraphy was repeated and kidneys were harvested for gross and microscopic examination. The risk of focal scarring corresponded to the severity of the initial acute pyelonephritic lesion, based on the percentage of renal parenchyma involved. In kidneys with mild and moderate acute pyelonephritic lesions, antibiotics alone were equally effective in preventing scarring when compared to treatment with antibiotics and steroids. However, severe pyelonephritic lesions were three times as likely to heal without scarring in animals treated with antibiotics in conjunction with steroids as compared to antibiotics alone.[224]

Detection of acute pyelonephritis

Dimercaptosuccinic acid (DMSA) renal scan

The diagnosis of acute pyelonephritis traditionally has been made on the basis of the classic signs and symptoms of fever and flank pain or tenderness asssociated with pyuria and positive urine culture. However, accurate diagnosis based solely on these parameters is often difficult, particularly in neonates and infants.[53,225] Despite the fact that the majority of patients (50–80%) with fever and systemic clinical findings consistent with acute pyelonephritis have abnormal DMSA scan findings, there is still a high false-positive and/or -negative rate based on routine clinical and laboratory parameters, including fever, elevated WBC, elevated CRP, elevated ESR, and the presence of VUR.[183]

Direct techniques have been used to localize the level of UTI to the upper or lower urinary tract. These include split-urine cultures collected by ureteral catheterization, bladder washout, and thin-needle aspiration of renal pelvic urine under ultrasonic guidance.[226,227] Although these efforts may accurately localize infection to the upper or lower urinary tract, they are obviously invasive and do not assess the extent of renal parenchymal involvement.

Renal cortical scintigraphy with ^{99m}Tc DMSA has emerged as the imaging agent of choice for the detection and evaluation of acute pyelonephritis and renal scarring in children. Early clinical reports showed that renal cortical scintigraphy using ^{99m}Tc DMSA or glucoheptonate was significantly more sensitive than IVU and renal sonography in the detection of acute pyelonephritis.[228–230] Subsequently, to evaluate the true sensitivity and specificity of renal cortical scintigraphy, experimental studies in an animal model were conducted using strict histopathologic criteria as the standard of reference.[231,232] In these two investigations, pyelonephritis was created in young piglets by surgically inducing unilateral VUR of infected urine. Typical DMSA renal scan findings of acute pyelonephritis included focal areas of diminished uptake of DMSA with preservation of the renal contour (Figure 7.8).[233] The DMSA scan was determined to be highly sensitive and reliable for the

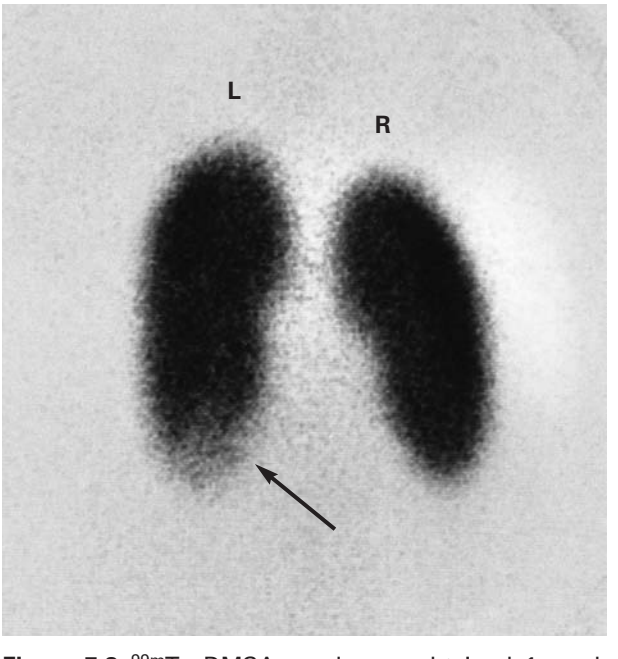

Figure 7.8 ^{99m}Tc DMSA renal scan obtained 1 week after introduction of infection in young pig with experimentally produced left vesicoureteral reflux. Focal decrease in uptake with preservation of renal contour is noted in left lower pole (arrow). Pathologic examination confirmed left lower pole pyelonephritis. (Reprinted from Rushton and Majd,[233] with permission.)

detection and localization of experimental acute pyelonephritis, with a sensitivity of 87–89% and specificity of 100% in both. When individual pyelonephritic lesions were analyzed, DMSA scan findings correlated with histopathologic changes with an overall agreement rate of 89–94%. Those lesions not detected were microscopic foci of inflammation not evident on gross examination and not associated with significant parenchymal damage.

Not only is DMSA scintigraphy highly sensitive and specific for the diagnosis of acute pyelonephritis but it also provides important information regarding renal function and the extent of renal parenchymal inflammation. Documentation of renal parenchymal damage associated with acute pyelonephritis is fundamental to understanding the roles of infection and VUR in the etiology of pyelonephritis and renal scarring.

Single-photon emmision computed tomography (SPECT)

The application of SPECT to DMSA scintigraphy reportedly further enhances the sensitivity of DMSA in the detection of acute pyelonephritis.[234–236] In clinical studies, a greater number of defects have been detected by SPECT compared with standard pinhole imaging. Obviously, in these clinical trials, histopathologic confirmation of the abnormal findings demonstrated by renal scintigraphy was not possible. To further evaluate the accuracy of SPECT imaging in the detection of acute pyelonephritis, SPECT was compared with pinhole imaging of DMSA renal scans for the detection and localization of acute pyelonephritis in 16 piglets (32 kidneys) with bilateral reflux of infected urine.[237] Animals were evaluated with both imaging modalities immediately prior to sacrifice at 1, 2, 3, and 10 days following the introduction of infection into their bladders. The overall sensitivity for detection of affected renal zones with histologic evidence of pyelonephritis was 86% for pinhole imaging and 91% for SPECT. The specificity was 95% for pinhole imaging and 82% for SPECT. Overall accuracy for the presence or absence of kidney involvement was 88% for both (Figure 7.9). Thus, SPECT imaging appears to be slightly more sensitive than standard pinhole imaging, but its application may result in more false-positive findings. Furthermore, it is easier to differentiate acute inflammatory changes from chronic renal scarring with pinhole imaging. Whether pinhole or SPECT imaging is utilized is to some extent dependent on the availability and experience of the imaging unit.

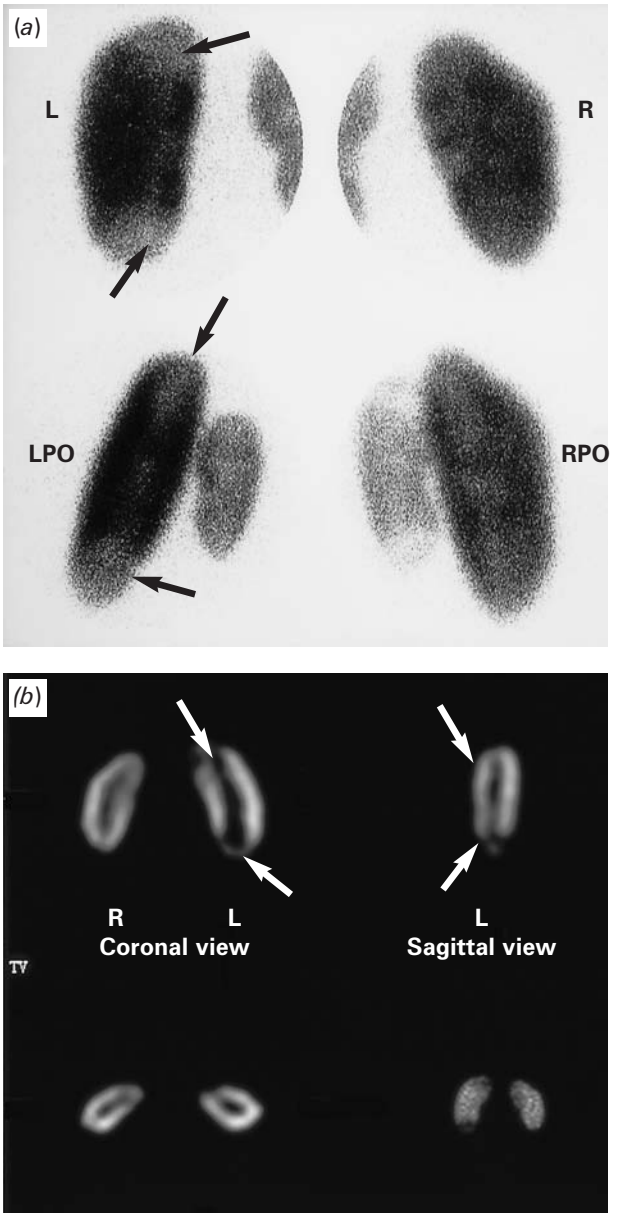

Figure 7.9 (*a*) Posterior and posterior oblique pinhole and (*b*) coronal and sagittal SPECT images of ^{99m}Tc DMSA renal scan in a young pig with bilateral vesicoureteral reflux and acute left pyelonephritis 48 h after introduction of *E. coli* broth into the bladder. Photopenic lesions in the left upper and lower poles are demonstrated by both modalities (arrows).

Sonography and intravenous pyelography (IVP)

Several clinical studies have clearly demonstrated that renal sonography is not as reliable as DMSA scintigraphy for the detection of acute pyelonephritis.[238–244]

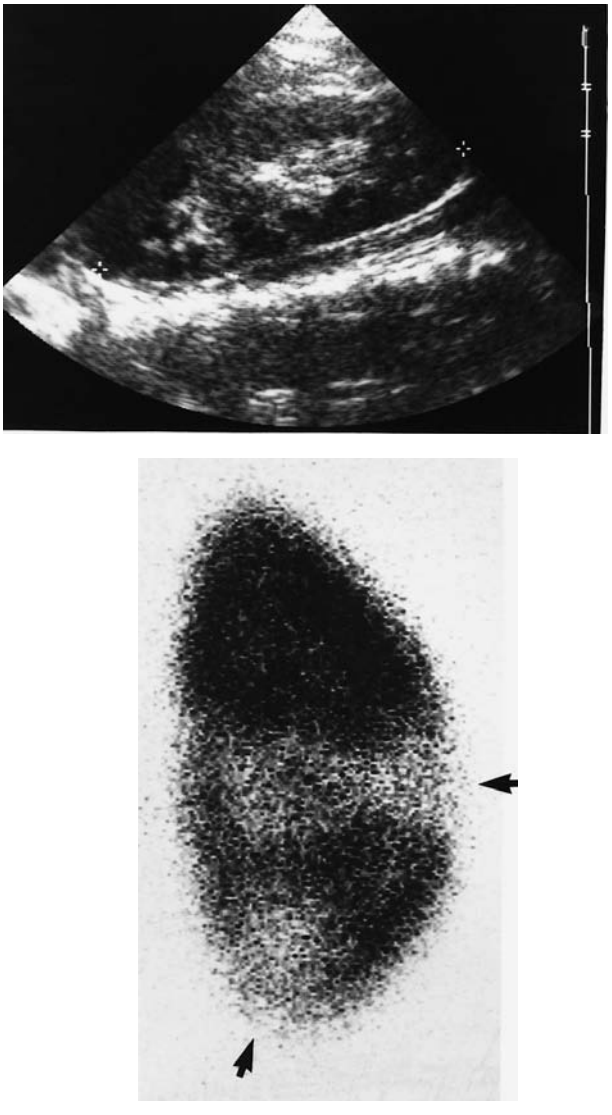

Figure 7.10 Normal sonogram and grossly abnormal ^{99m}Tc DMSA renal scan of right kidney showing large mid-zone and moderate lower pole photopenic lesions characteristic of acute pyelonephritis in a 4-year-old girl who presented with her first documented febrile UTI (arrows). VCUG was negative for vesicoureteral reflux.

In one prospective study of 91 children with culture-documented febrile UTIs, DMSA renal scans showed changes consistent with acute pyelonephritis in 63% of the patients.[238] In contrast, sonography revealed changes consistent with acute pyelonephritis in only 39% of the same patients. More recently, MacKenzie et al prospectively compared the results of renal ultrasound with DMSA renal scans in 112 children with their first documented symptomatic UTI.[239] Although ultrasound was particularly effective in detecting dilatation of the collecting system and renal swelling, it failed to detect over half of those patients with abnormal DMSA scans demonstrating photon-deficient areas consistent with acute inflammatory changes of pyelonephritis (Figure 7.10). Intravenous pyelography has been shown to be very insensitive for the detection of acute pyelonephritis.[245]

Other renal isotopes

The usefulness of an early ^{99m}Tc mercaptoacetyltriglycine(MAG3) renal scan in predicting renal alterations seen on DMSA renal scans has been evaluated by Piepz et al.[244] These investigators concluded that the accuracy of the MAG3 renal scan was population dependent. When the DMSA scan was normal or very abnormal, the MAG3 image correctly reflected the findings of the DMSA renal scan. However, when the DMSA abnormalities were less pronounced, the early MAG3 scan failed to detect about half of the cases.

^{99m}Tc glucoheptonate has also been used in the detection of acute inflammatory changes associated with acute pyelonephritis.[229,230,247] Although the sensitivity and specificity of ^{99m}Tc-labeled glucoheptonate and DMSA have not been directly compared, certain observations can be made. Approximately 60% of the administered dose of ^{99m}Tc DMSA is tightly bound to the proximal tubular cells, and only a small amount is excreted slowly in the urine. Consequently, DMSA allows for excellent visualization of the renal parenchyma without interference from retained tracer in the collecting systems. In contrast, only about 20% of the administered dose of ^{99m}Tc glucoheptonate is firmly bound to the tubular cells. Most of the administered dose is excreted in the urine, which allows for moderately good visualization of the renal collecting systems on the early images. This additional information makes glucoheptonate the preferred agent of some clinicians.[247] However, the quality of the delayed renal cortical images is clearly better with DMSA.

MRI, CT scans, power Doppler sonography

The use of magnetic resonance imaging (MRI) with UTIs has also been reported. In a clinical study for detection of acute pyelonephritic damage in children, the sensitivity and specificity of gadolinium-enhanced MRI was equal to that of ^{99m}Tc DMSA scanning.[246] In a more recent animal study, SPECT imaging using DMSA was compared with spiral computed tomography (CT) scanning (pre- and postcontrast), gadolinium-enhanced MRI, and power Doppler sonography in 35 infected piglets with 70 refluxing

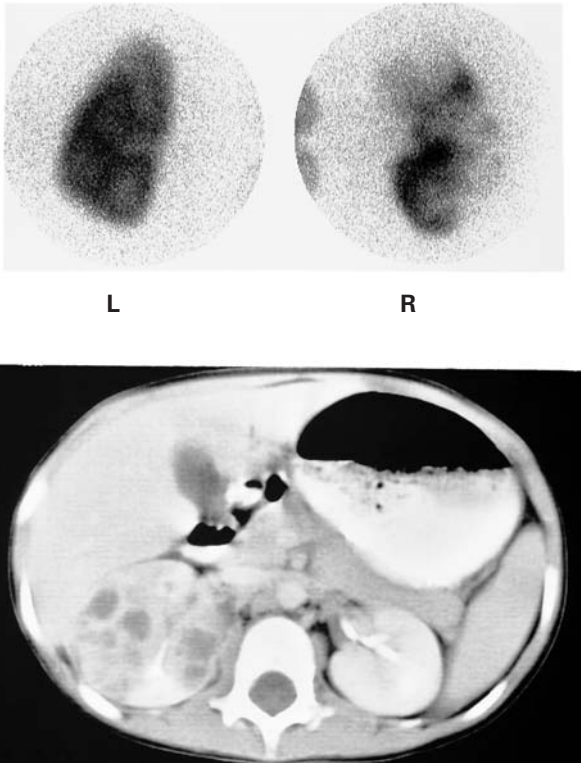

Figure 7.11 Severe multifocal acute pyelonephritis in the right kidney is well demonstrated on both a ^{99m}Tc DMSA renal scan and CAT scan in a 3-year-old girl with her first febrile UTI. Photopenic areas on DMSA scan correspond to attenuated hypodense lesions on CAT scan. Note diffuse right renal swelling on CAT scan.

Figure 7.12 Gadolinium-enhanced MRI in a young pig with bilateral vesicoureteral reflux (VUR) demonstrates multiple acute pyelonephritic lesions in both kidneys as evidenced by bright parenchymal lesions (arrows).

kidneys.[249] The imaging modalities were interpreted independently and compared in a blinded fashion with histopathologic findings. SPECT DMSA, spiral CT, and MRI were equally sensitive and reliable for the detection and localization of acute pyelonephritis (Figures 7.11 and 7.12). Power Doppler sonography was significantly less accurate in this porcine model. However, a recent clinical study comparing Doppler sonography to DMSA scanning in 62 children, found favorable positive- and negative-predictive values (93.1% and 85.7%, respectively) for Doppler studies.[250] Nevertheless, with increased experience and enhanced applications, clinical use of spiral CT and MRI is likely to gain popularity in the evaluation of the pediatric urinary tract.

Evaluation of the child with urinary tract infection

Controversy continues to exist regarding when and how a child with documented UTI should be evaluated. A recent systematic overview of the literature to assess the evidence on which current recommendations for routine diagnostic imaging are based found that there were no controlled trials or analytic studies which evaluated the need for routine diagnostic imaging.[251] All reports were descriptive and the majority were retrospective. Furthermore, none provided evidence of the impact of routine imaging on the development of renal scars and clinical outcomes in children with their first UTI.

Most pediatric urologists would agree that all children under 5 years of age, boys of any age, and all with febrile UTI or documented acute pyelonephritis should be evaluated when infection is first recognized. The key to this recommendation is adequate documentation of UTI.

The arguments in favor of early evaluation of young children following their first documented UTI are based on both experimental and clinical data. Clinical and experimental studies have proved that significant renal scarring can occur after a single UTI.[252,253] A higher incidence of renal scarring has been reported in children with VUR and recurrent UTIs than in those with reflux who have had only a single infection.[254,255] Similarly, Jodal reported a strong association between the number of pyelonephritic episodes and the incidence of renal scarring.[5] Recurrence of UTI within 1 year of a

preceding infection occurs in approximately 30% of girls with one, 60% with two, and 75% with three prior infections.[11] Furthermore, the non-specificity of signs and symptoms that typically accompany urinary infection in infants and toddlers often makes it impossible to determine whether an infection actually represents the first episode.[11] Additional justification for early evaluation is based on the high yield of uropathology obtained from the evaluation of children with culture-documented UTIs. Cystography in Caucasian girls with symptomatic UTIs consistently demonstrates the presence of VUR in approximately 30–50% of cases, regardless of whether the study is requested by pediatric subspecialists (urology/nephrology) or other clinicians (pediatricians, family practitioners, adult urologists).[5,256,257] The exception is found in African-American girls with UTI in whom the relative incidence of VUR is about one-third that of Caucasian girls.[7,124] Unfortunately, other clinical parameters have proven unreliable in distinguishing those children with UTI who also have VUR.[118] All of the aforementioned factors offer a convincing argument to pursue early evaluation of young children following their first documented UTI. Waiting until a child has had two or more UTIs before proceeding with evaluation clearly increases the risk that permanent scarring, which might have otherwise been prevented, may occur.

History

Evaluation of the child with a UTI should always begin with a careful history. Because bladder emptying plays an important role in the etiology and prevention of UTI, a careful voiding history is an essential component of the work-up of toilet-trained children with UTIs.[258] Many of these children also have associated constipation that may only be detected when specific questions are directed toward the patient and parents. Family history should also be obtained, since heredity appears to play a role in an individual's predisposition toward infection, as evidenced by familial studies showing an increased incidence of bacteriuria in female siblings.[123] Similarly, a significant familial risk for VUR has been demonstrated when a sibling or parent has a history of having reflux.[259]

Physical examination

Physical examination of the child presenting with UTI should include palpation of the abdomen for flank masses, bladder distention, and/or abdominal masses caused by fecal impaction. Although genital examination in boys should exclude significant meatal stenosis, this is an extremely rare cause of UTI. Considering the epidemiologic evidence demonstrating an increased risk for UTI in uncircumcised boys, the circumcision status is of particular importance in male infants. Abnormal genital findings in girls include vulvovaginitis or the presence of labial adhesions that might predispose the child to perineal colonization by bacteria. More often labial adhesions increase the risk for contamination of 'clean-catch' urine specimens for culture. In children with a significant history of voiding dysfunction associated with constipation and/or encopresis, a brief neurologic examination should include evaluation of perineal sensation, of peripheral reflexes in the lower extremities, and of the the lower back for sacral dimpling or cutaneous abnormalities that suggest an underlying spinal abnormality (occult spinal dysraphism). Rectal examination for fecal impaction may be indicated if the history suggests severe constipation or encopresis.

Imaging

Recommended imaging studies for a child with a history of a culture-documented UTI are based, to some extent, on the experience of the radiologist and the availability of imaging modalities. Age, gender, race, and the type and frequency of UTIs must also be taken into consideration. For many years, the emphasis on the investigation of the child with UTI has centered on diagnosis of VUR. Some authors have suggested that the emphasis should be on whether the child has renal scarring or is at risk for renal scarring.[260–265] They argue that if there is no evidence of renal damage at the time of the infection, then it is not necessary to evaluate for VUR as the risk for future renal scarring is minimal. Consequently, these authors have recommended that the initial evaluation in children older than 1–2 years should be of the kidney, including sonography to exclude surgical conditions which predispose to infection and DMSA scintigraphy to detect acute pyelonephritic inflammation. With this approach, cystography is reserved for infants under 1–2 years and older children with abnormal DMSA scan findings or recurrent UTIs. One critical review found that such an approach might miss approximately 8% (7/80) of children with grade III VUR who have normal DMSA scans. However, VUR resolved or significantly improved in 86% (6/7) and no child had recurrent UTI.[266] This algorithm is further supported by the observations that

while clinically significant acute lesions may be present in the presence or absence of VUR, significant renal scarring is most likely to occur in those with grade III and IV VUR.[267] In contrast, most American urologists, pediatricians, and radiologists still recommend that the evaluation of infants and toddlers should always include a cystogram to detect the presence of VUR, ureteroceles, posterior urethral valves in boys, or bladder wall thickening and a sonogram to look for obstruction, hydronephrosis, or other congenital malformations.[268,269] Whether one accepts the recommendation that DMSA scintigraphy should precede voiding cystourethrography in the evaluation of children with UTIs is determined in part by the goal of management of these patients. For those whose ultimate goal of treatment is the cessation of VUR, when present, then VCUG will continue to be the initial study of choice. For others, whose primary goal is the detection and future prevention of pyelonephritis and new renal damage, DMSA scintigraphy may well replace VCUG as the initial investigation of children with symptomatic UTIs. It should be recognized that, to date, no studies have analyzed the relative advantages of any specific imaging approach with regard to documentation of their impact on the development of renal scars or other clinical outcomes.[251]

Timing of evaluation

The timing of evaluation is often a concern of the urologist, radiologist, and pediatrician. Many recommend that children requiring hospitalization should at least be screened for obstruction with an ultrasound scan prior to discharge. For patients evaluated with cystography, it has been suggested that this be delayed 4–6 weeks following the acute infection to avoid demonstrating transient mild reflux secondary to inflammatory changes of the ureterovesical junction. However, it is rare for reflux to be detected during infection and then disappear after treatment.[270,271] Furthermore, since the significance of reflux is greatest at the time of bacterial infection, demonstration of even transient reflux may be very meaningful. One potential disadvantage of obtaining a cystogram early in the course of a febrile infection is that ureteral dilatation secondary to the effect of endotoxins may result in overestimation of the grade of reflux.[272,273] Nevertheless, a prolonged 'waiting period' is not necessary. The cystogram can usually be performed whenever the patient is no longer symptomatic and when the urine is sterile.[274] Regardless of when studies are performed, antibiotic prophylaxis should be maintained until that time, particularly in infants or in children with a previous febrile UTI, in order to prevent reinfection.[253,274]

For patients evaluated with DMSA renal scintigraphy, the timing of the study is in part determined by the reason for the study. If one is attempting to document acute pyelonephritic inflammatory changes, the DMSA renal scan is best obtained early within the first several days of the acute episode.[275] However, if the primary goal is to document irreversible renal scarring following an episode of infection, then the study should be delayed for 6 months following the acute infection since transient acute changes on DMSA scans can persist for up to 5 months prior to resolving.[276]

Cystography

Both direct and indirect cystography techniques are used. Direct cystography involves filling the bladder by urethral catheterization or percutaneous suprapubic infusion. Both standard contrast medium and radiolabeled nuclides are satisfactory. In boys, contrast cystography is preferred because it provides for visualization of the urethra and for grading reflux (Figure 7.13).[277] It is also more reliable for detecting duplication, ureteral ectopia with or without ureteroceles, posterior urethral valves, bladder trabeculation, bladder diverticula, and foreign bodies. Many also prefer its use for the initial examination in girls because the grade of reflux can be determined. Several methods for grading are used. The International Reflux Study method is most widely accepted.[277] A disadvantage of standard contrast cystography is the high gonadal radiation dose it entails, particularly with multiple studies or fluoroscopic monitoring. The addition of digital fluoroscopy reduces gonadal radiation exposure.[278] Using a low-dose fluoroscopic system with a computer-based video frame grabber, the ovarian radiation dose has been reported to compare favorably to radionuclide cystography.[279]

Direct radionuclide cystography allows continuous monitoring for reflux throughout the study without additional radiation exposure. It is reported to be more sensitive than contrast cystography for the diagnosis of reflux.[280–282] Whereas precise grading of VUR is limited, it can usually be categorized as mild, moderate, or severe (Figure 7.14). Although radionuclide cystography has been criticized for being unable to detect grade I/V VUR, a recent study found that direct radionuclide cystography demonstrated VUR

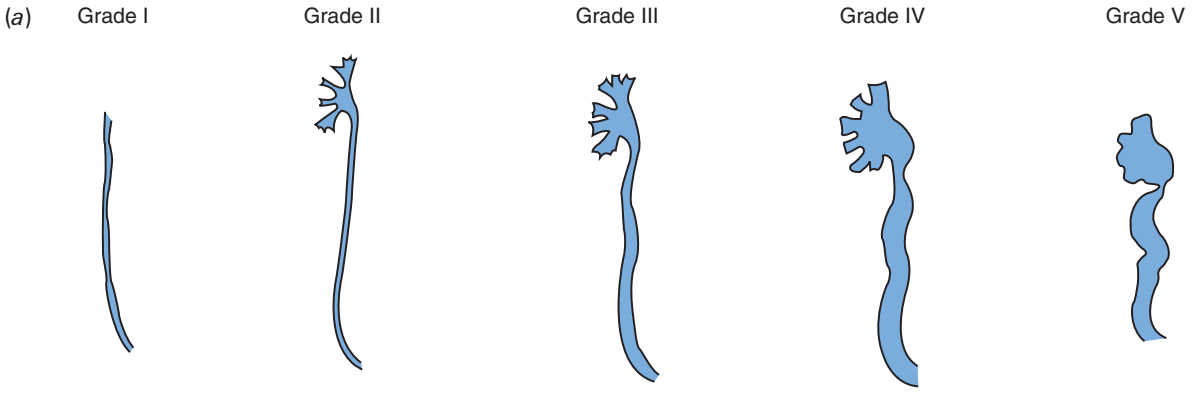

Figure 7.13 (*a*) International classification of vesicoureteral reflux: grade I, ureter only; grade II, ureter, pelvis, calices, no dilatation, normal caliceal fornices; grade III, mild or moderate dilatation and/or tortuosity of ureter, and mild or moderate dilatation of the pelvis, but no or slight blunting of the fornices; grade IV, moderate dilatation and/or tortuosity, of ureter and mild dilatation of renal pelvis and calices, complete obliteration of sharp angle of fornices but maintenance of papillary impressions in majority of calices, grade V, gross dilatation and tortuosity of ureter, gross dilatation of renal pelvis and calices, papillary impressions are no longer visible in majority of calices. (Modified from International Reflux Committee[277].) (*b*) Voiding cystogram shows grade III VUR on the right with moderate dilatation and tortuosity of ureter, moderate dilatation of the pelvis, but slight blunting of the fornices. Grade IV reflux is seen on the left with similar dilatation of the ureter and pelvis but with obliteration of sharp angle of fornices. Papillary impressions are maintained in the majority of the calices.

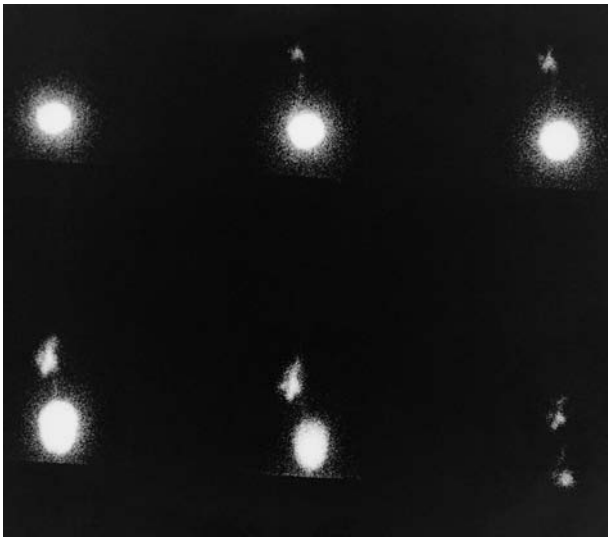

Figure 7.14 Isotope cystogram demonstrates mild left vesicoureteral reflux during filling (*top row*), which becomes moderate reflux when the bladder is full and during voiding (*bottom row*).

to the renal pelvis in all 17 kidneys with grade I/V VUR on contrast cystography.[283] The radiation dose from radionuclide cystography reportedly is 50–200 times less than that with standard techniques using contrast cystography, making it ideal for the follow-up of children with VUR and for following results of antireflux surgery.[284]

Indirect radionuclide cystography uses ^{99m}Tc DTPA (technetium-99m-labeled diethylenetriamine pentaacetic acid), which is excreted by glomerular filtration. The presence of reflux can be assumed when radioisotope counts increase in the renal areas after voiding. Indirect cystography is less reliable for the detection of VUR than direct radionuclide cystography, with false-negative rates ranging from 22 to 51%.[285,286] More recently indirect radionuclide cystography using ^{99m}Tc MAG3 was reported to also be unreliable for the detection of VUR, missing approximately two-thirds of refluxing kidneys[286] (Figure 7.15).[287]

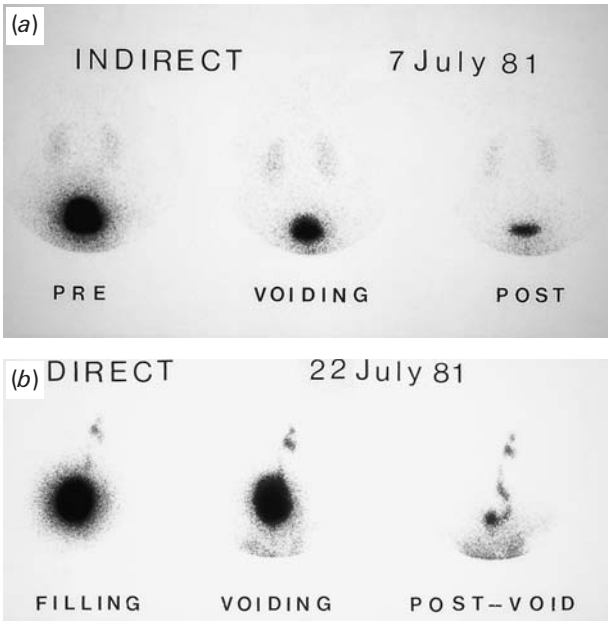

Figure 7.15 (*a*) False-negative indirect radionuclide cystogram in a 6-year-old girl. Images before and after voiding demonstrate no evidence of vesicoureteral reflux. (*b*) Selected images from a direct radionuclide cystogram in the same patient obtained 2 weeks after the indirect study show moderate reflux on the right during filling and voiding, and after voiding. Upper tract imaging

Recommendations for evaluating the upper urinary tract in children presenting with UTI also vary from institution to institution. The ideal study should be painless, safe, cost-effective, and associated with minimal or no radiation and yet should be capable of detecting clinically significant structural malformations as well as renal scarring. Unfortunately, such an all-encompassing study does not exist.

One approach is initial screening of all patients being evaluated for a history of UTI with a renal–bladder sonogram.[288] In children, sonography has been found to be as sensitive as IVP for the detection of any significant renal abnormality, except for uncomplicated duplication anomalies and focal renal scarring.[288–291] Sonography is painless, non-invasive, simple to perform, radiation-free, and independent of renal function. It is critical that appropriate images of the ureters, bladder, and true pelvis be routinely obtained in order to detect the presence of ureteroceles or dilated ureters secondary to ureteral ectopia, ureterovesical junction obstruction, or severe VUR. To do so, the bladder should be full during the examination. A postvoiding residual also can be demonstrated at the completion of the study. In the absence of reflux, hydronephrosis revealed by sonography is best evaluated with diuretic renography using ^{99m}Tc DTPA or ^{99m}Tc MAG3.[292] When combined with the findings of the renal bladder sonogram, the site of obstruction can be reliably determined in almost all cases.[136] When needed, further evaluation is best accomplished with percutaneous antegrade pyelography and pressure–perfusion studies (Whitaker test).

Considering the very low incidence of surgically significant hydronephrosis presenting as UTI, some authors have questioned the role of sonography in the investigation of UTIs in children, recommending instead a cortical renal scan as the initial upper tract study of choice.[239,247,293,294] Still other authors have suggested a tailored approach to the evaluation of children with UTI, beginning with a voiding cystogram.[295,296] If no reflux is present, a renal ultrasound scan is done to exclude hydronephrosis or other upper tract malformations. Otherwise, if reflux is demonstrated, the next study would be a renal cortical scan to detect renal scarring (Figure 7.16).[297] This approach seems reasonable for the majority of cases.

In clinical practice, the use of DMSA scintigraphy is best reserved for those occasions when it will influence management. DMSA scintigraphy can be helpful in the initial evaluation and follow-up of patients with VUR. For example, not all patients with VUR and breakthrough UTIs require immediate surgical intervention, particularly those with asymptomatic bacteriuria[298] (Figure 7.17). In contrast, when new renal damage associated with a breakthrough UTI is objectively demonstrated by DMSA scintigraphy, anti-

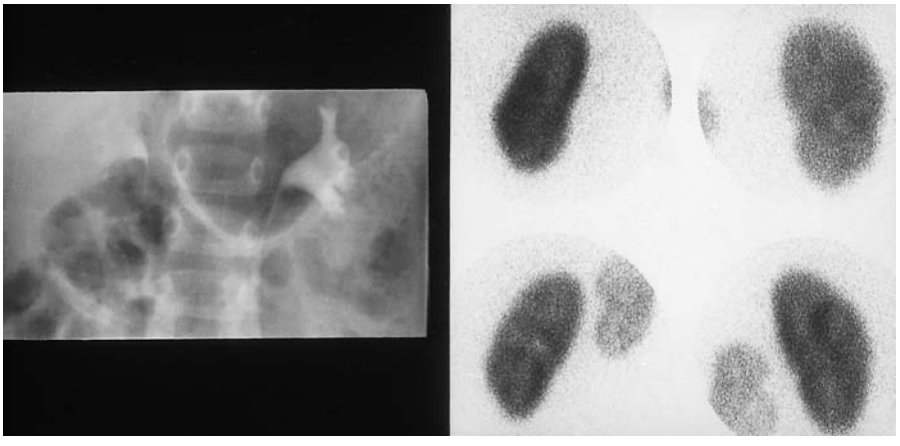

Figure 7.17 A 3-year-old girl with bilateral grade II vesicoureteral reflux (*left*) developed a breakthrough febrile UTI while on antibiotic prophylaxis. A ^{99m}Tc DMSA renal scan (*right*) at the time of the infections did not demonstrate any evidence of pyelonephritis or scarring. Her prophylaxis was changed and repeat isotope cystogram 1 year later revealed complete resolution of her reflux.

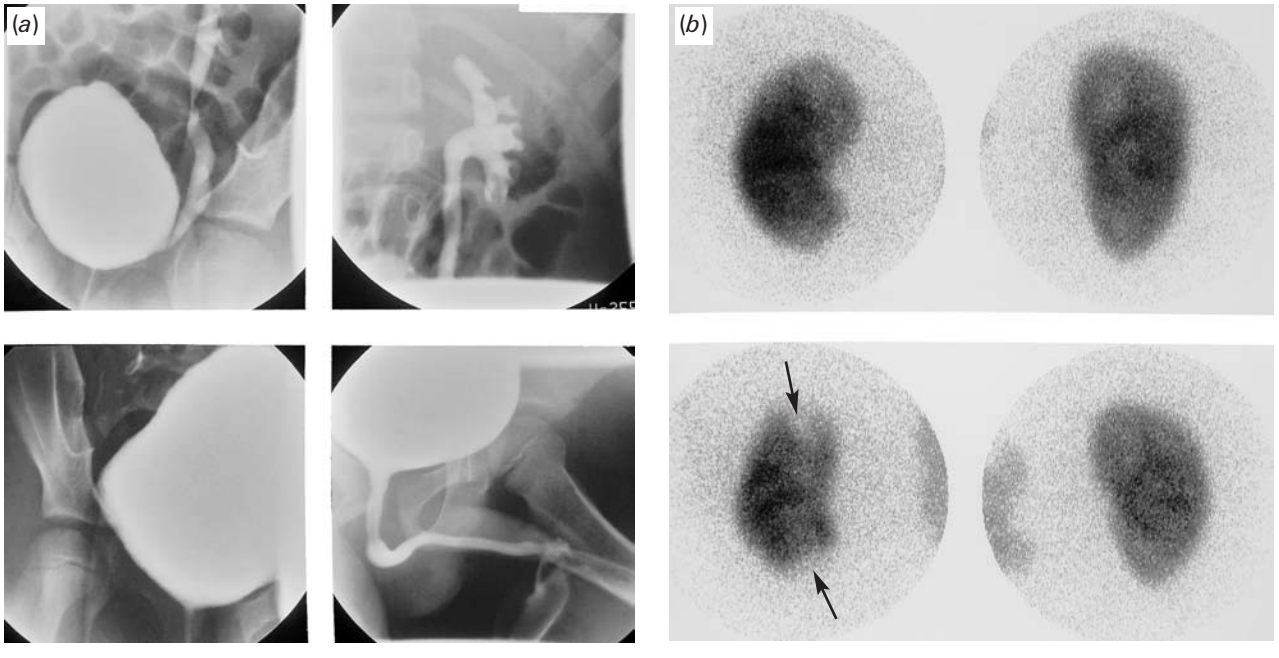

Figure 7.18 A 2-year-old girl presented with her first culture- documented UTI. (*a*) Voiding cystogram demonstrates left grade III vesicoureteral reflux. (*b*) (*Top*) Initial ^{99m}Tc DMSA renal scan was normal. (*Bottom*) Repeat ^{99m}Tc DMSA renal scan following a breakthrough febrile UTI reveals acute pyelonephritic changes in the left upper and lower poles (arrows). Left ureteral reimplantation was performed.

reflux surgery becomes imperative (Figure 7.18). It has been suggested that DMSA scan abnormalities are predictors of breakthrough UTIs (odds ratio 6.0) in children with VUR.[299] Likewise, DMSA scintigraphy is important in the initial evaluation of infants with prenatally detected VUR, as many of these patients will have significant congenital reflux nephropathy.

DMSA scintigraphy is also particularly helpful for establishing the correct diagnosis of pyelonephritis in situations when the diagnosis is unclear based on clinical and laboratory findings, such as in neonates and young infants. Not infrequently, the diagnosis in these young children is obscured by improper urine collection techniques or the institution of antibiotics before

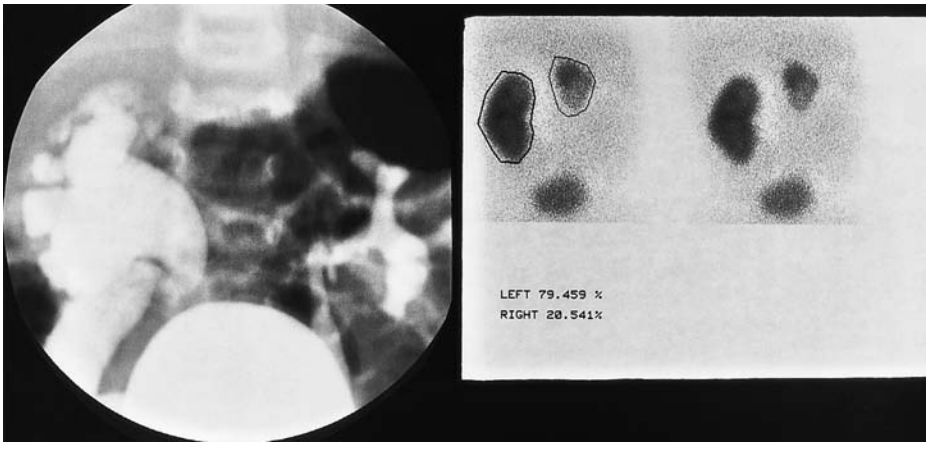

Figure 7.19 One-month-old boy with prenatally detected hydronephrosis. (*Left*) Voiding cystogram shows right grade V (note intrarenal reflux) and left grade III vesicoureteral reflux. (*Right*) ^{99m}Tc DMSA scan reveals a hypoplastic right kidney with markedly reduced differential renal function. He had been on antibiotic prophylaxis since birth and urine cultures were negative.

a urine culture is obtained. Other difficult diagnostic situations include children with neuropathic bladders managed by clean intermittent catheterization.[300,301] These children are usually chronically bacteriuric; therefore, the diagnostic significance of a positive urine culture at the time of a febrile episode is lost.

Renal scarring

Partly because most renal scars that are detected in children with prior urinary tract infection(s) have become established by the time of initial evaluation, the pathogenesis of renal scarring remains controversial.[15,207,254] Furthermore, it has become increasingly clear that the term renal scarring has been applied to the end result of more than one type of pathophysiologic process, including both abnormalities that are congenital and those that are acquired postnatally. The correlation between the severity of VUR and renal scarring is also well established.[5,302–304] Although the vast majority of cases of renal scarring associated with VUR are detected during the evaluation of children with UTI, recent studies of prenatally detected hydronephrosis secondary to high-grade VUR have also confirmed cases of congenital functional abnormalities documented by DMSA renal scintigraphy even in the absence of infection[305–10] (Figure 7.19). Furthermore, a higher prevalence of renal scarring has been reported in children with secondary VUR associated with functional or anatomic bladder outlet obstruction, including posterior urethral valves and neuropathic bladders,

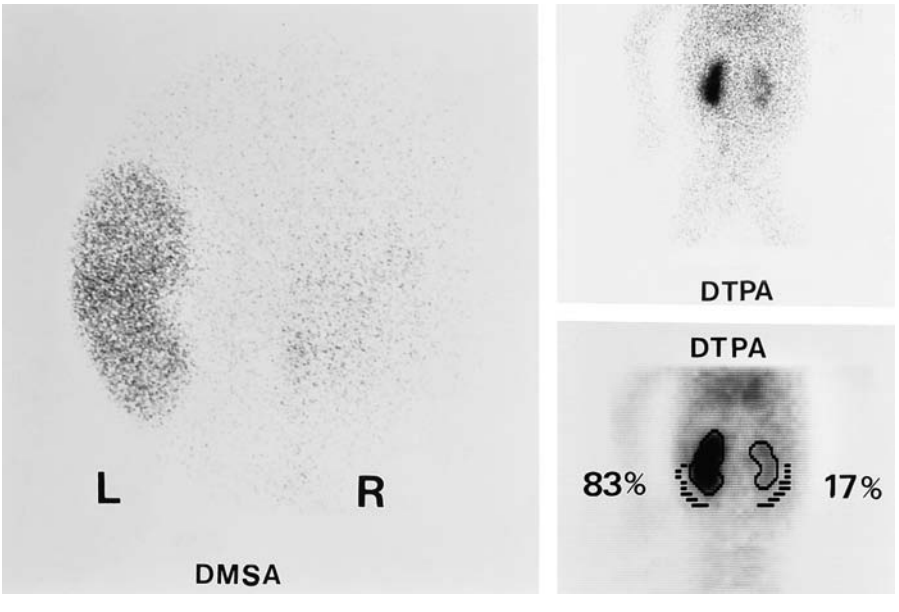

Figure 7.22 A 9-month-old girl hospitalized with her first febrile UTI. VCUG demonstrated right grade IV vesicoureteral reflux. Sonography showed moderate right hydronephrosis. (*a*) Initial ^{99m}Tc DMSA renal scan at the time of hospitalization demonstrates marked diffuse decreased uptake (function) in the right kidney, consistent with acute pan-pyelonephritis. (*b*) Follow-up ^{99m}Tc DTPA renal scan 1 month later shows partial recovery of function, but the kidney is contracted and scarred with a differential function of only 17%. (Reprinted from Rushton,[297] with permission.)

than in children with primary VUR.[54] Lumping renal sequelae from all of these pathophysiologic entities under the terms 'renal scarring' or 'reflux nephropathy' has hampered attempts at understanding the pathogenic mechanisms involved.

The critical role that infection plays in the pathogenesis of renal scarring associated with reflux was clarified in Ransley and Risdon's classic experimental studies of VUR in piglets.[311] They demonstrated that, in the face of VUR and normal voiding pressures, renal scarring occurs only when urinary infection is present. Reflux in the absence of infection caused renal changes only when bladder outlet resistance was increased, so that obstruction, not reflux, was the pathophysiologic explanation for renal damage. It was suggested that the portions of the kidney at risk for scarring are those susceptible to pyelotubular backflow (intrarenal reflux), based on papillary morphology and configuration (Figures 7.20 and 7.21).[312]

Clinically, new or progressive scarring is almost always associated with a history of UTI. Experimental studies and clinical experience have shown that a single episode of pyelonephritis can lead to significant renal damage (Figure 7.22).[252,313] Furthermore, a

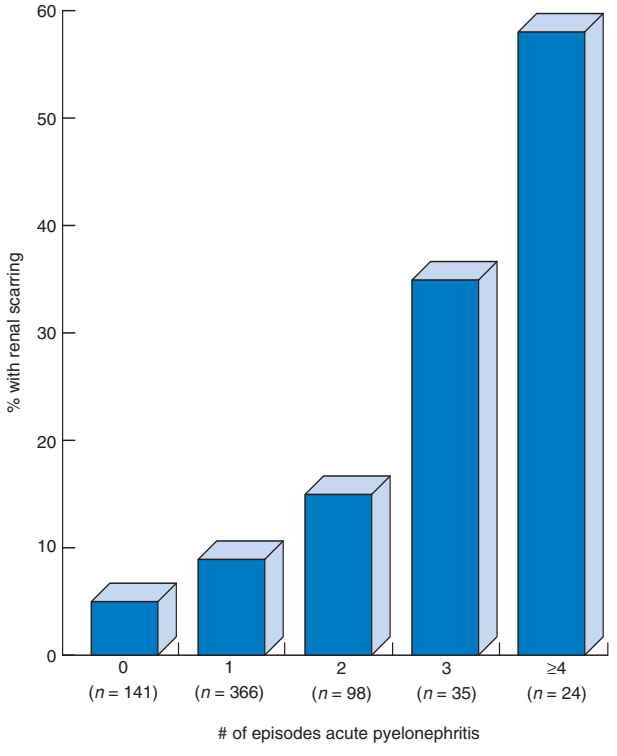

Figure 7.23 Relationship of renal scarring to number of episodes of acute pyelonephritis. (Adapted from Jodal.[5])

clear association between the number of pyelonephritic attacks and incidence of renal scarring has been reported (Figure 7.23).[5,22,254] Both experimental and clinical studies have also shown that some renal scarring can be prevented or diminished by early antibiotic treatment of acute pyelonephritis (Figures 7.24 and 7.25).[31,252,315–316] Furthermore, when reflux is present, progressive renal scarring can be successfully prevented by keeping the patient free of infection.[303,304,317] Based on all of the above, it is clear that infection, not reflux alone, is a prerequisite for acquired renal scarring.

Congenital renal scarring associated with reflux

Severe reflux may be associated with significant renal dysplasia thought to result from abnormal induction of the nephrogenic cord during embryogenesis.[318, 319] Several reports have described DMSA scan renal functional abnormalities in patients with primary VUR detected prenatally.[305–309] The reported incidence of renographic abnormalities in these studies has varied widely, ranging from 17% to 60%.[306–308] Many of these infants were evaluated by renal scintigraphy

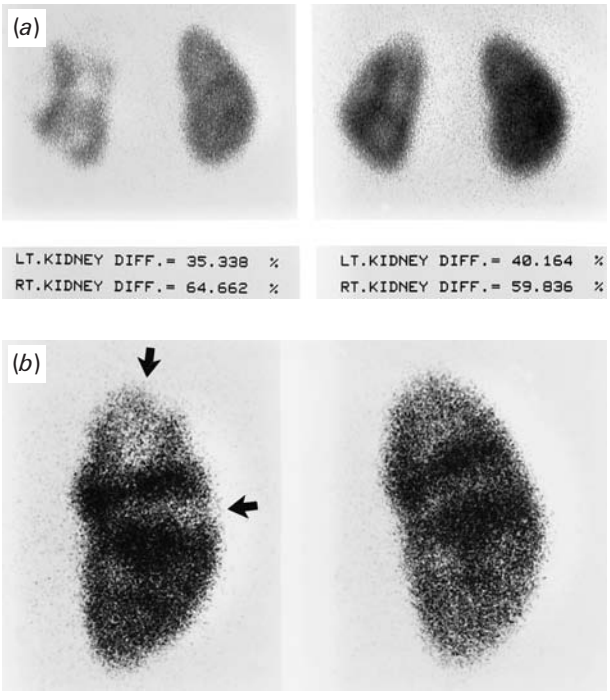

Figure 7.24 (*a*) ^{99m}Tc DTPA renal scan in a 3.5-year-old girl with left grade IV vesicoureteral reflux and multiple recurrent UTIs. (*Left*) Multifocal acute pyelonephritis is demonstrated in the upper and lower poles and mid-zone of the left kidney. (Reprinted from Rushton and Majd,[233] with permission.)

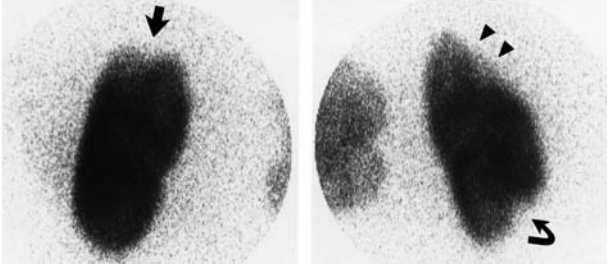

Figure 7.25 ^{99m}Tc DMSA renal scan in a 7-year-old girl 7 months after her first documented febrile UTI. A VCUG revealed bilateral grade II vesicoureteral reflux. Renal scarring is present in both kidneys. The left upper pole is flattened (arrow). There is a wedge-shaped defect in the right lower pole (curved arrow) and thinning of the right upper pole (arrowheads). (Reprinted from Rushton,[314] with permission.)

prior to any known episodes of infection, confirming that the functional abnormalities present at birth represent a congenital fetal nephropathy rather than a secondary acquired abnormality. In one study, nephrectomy specimens in a few of these severely 'scarred' kidneys with minimal function demonstrated severe dysplasia and growth arrest.[308] This would suggest that both congenital and acquired scarring may occur in the same kidney.

Imaging of renal scarring

In the past, the primary imaging modality for the detection of renal scarring was the intravenous pyelogram. However, limitations of the IVP have actually hindered our understanding of the pathogenesis of renal scarring. Although relatively sensitive for the detection of renal scarring, the IVP is very insensitive in the detection of acute pyelonephritis.[245] Furthermore, pyelographic evidence of new renal scarring may take 2 or more years to develop after a documented UTI.[253,320] Consequently, this has forced investigators to speculate retrospectively about the etiology of renal scarring.

In contrast, DMSA renal cortical scintigraphy is capable of detecting both the acute inflammatory changes of pyelonephritis and renal scarring. Several studies comparing the DMSA renal scan to the IVP in the detection of renal scarring have demonstrated a greater sensitivity with isotope imaging, especially in younger children.[242,321–325] Merrick et al compared the findings of IVP to DMSA scans in 79 children who had proven UTI and had been followed for a period of 1–4 years.[321] The sensitivity of IVP for the detection of renal scars was 80% and the specificity was 92%, whereas cortical scintigraphy had a sensitivity of 92% and a specificity of 98%. When both IVP and DMSA scintigraphy demonstrate scars, an excellent correlation on a site-by-site basis has been reported.[321–323,325,326] When compared with histology in an animal model, the sensitivity and specificity of the DMSA scan for the detection of renal scarring in 60 piglets with reflux and infected urine was 85% and the specificity was 97%.[327] Thus, DMSA renal cortical scintigraphy offers a superior opportunity to study the progression of renal damage or functional loss from the time of the initial insult until either complete healing or irreversible scarring develops.

Studies that have compared ultrasonography with DMSA scintigraphy for the detection of renal scarring have consistently reported greater sensitivity with DMSA renal scans.[239,242,243] In one study, Yen and associates compared ultrasound, IVP, and both planar and SPECT DMSA renal scintigraphy in the evaluation of 130 children with UTI (42 patients), VUR (37 patients), and unilateral or bilateral small kidneys (51 patients).[244] SPECT imaging of DMSA scans detected the highest number of defects, followed by planar imaging.

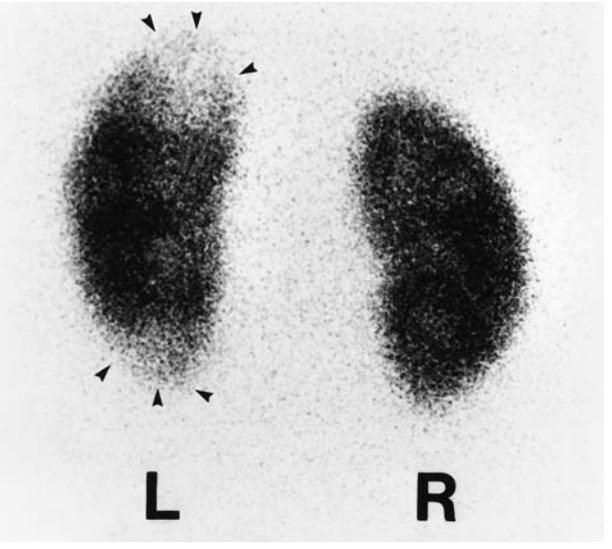

Figure 7.26 ^{99m}Tc DMSA renal scan demonstrates typical changes of acute pyelonephritis in the upper and lower poles of the left kidney. Diminished uptake of isotope is seen with an intact renal cortical outline without volume loss or contraction (arrowheads). (Reprinted from Cohen et al,[300] with permission.)

Renal scars detected by DMSA scintigraphy appear as focal or generalized areas of diminished uptake of radioisotope associated with loss or contraction of functioning renal cortex. This may appear as thinning or flattening of the cortex in some kidneys, while in others renal scars appear as classic discrete wedge-shaped parenchymal defects (see Figure 7.25). In more severe cases, generalized damage may be associated with multifocal or diffusely scarred kidneys and reduced differential renal function. In contrast, defects associated with acute pyelonephritis are more typically characterized by focal areas of diminished uptake but with preservation of the normal renal contour (Figure 7.26). Although it is often possible for an experienced observer to distinguish acute versus chronic lesions, it should be recognized that this differentiation may be less apparent in those kidneys with acute pyelonephritis superimposed on pre-existent renal scarring.

New or acquired scarring

Until recently a common assumption was that VUR was an absolute prerequisite for new or acquired renal

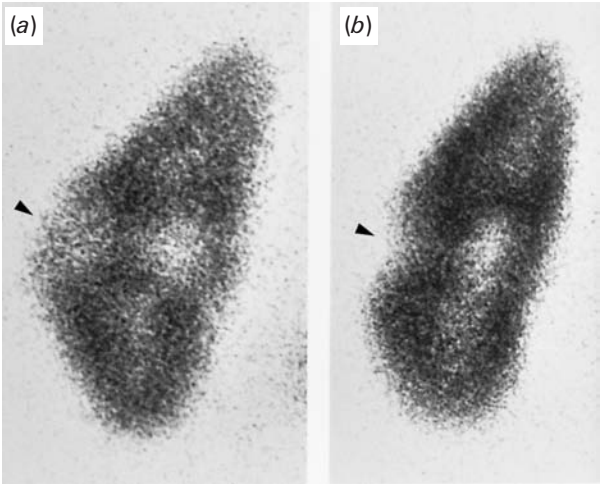

Figure 7.27 ^{99m}Tc DMSA renal scan in a 13-month-old girl with an acute febrile UTI. (*a*) Left posterior oblique view on the initial DMSA scan demonstrates acute pyelonephritis of the mid-zone of the left kidney evidenced by a photopenic lesion with preservation of the renal contour (arrowhead). (*b*) Follow-up DMSA renal scan reveals progression to renal scar in the exact same site characterized by contraction and loss of functioning renal cortex (arrowhead). (Reprinted from Rushton et al,[54] with permission.)

scarring. This mindset was further perpetuated by earlier investigations of new or acquired renal scarring, most of which focused retrospectively on patients with known VUR. However, in one earlier study which selected patients on the basis of infection alone, only half of the 37 children who formed new renal scars had VUR.[316]

Several investigators have now evaluated the evolution of the acute inflammatory changes associated with pyelonephritis using serial DMSA renal scans.[233,276,328–330] The interval from the initial DMSA scan obtained at the time of acute infection until the repeat scan ranged from 3 months to 2 years. Acute DMSA renal scan defects persisted as renal scarring in 36–52% of kidneys. The sites of new renal scarring corresponded exactly to those sites of acute pyelonephritis seen on the initial DMSA renal scans, confirming the primary role of the acute inflammatory response to infection in the etiology of acquired renal scarring (Figure 7.27). Contralateral normal kidneys and initially uninvolved areas of abnormal kidneys have almost always remained normal on follow-up DMSA renal scans. Surprisingly, reflux has been present in only 25–50% of kidneys that developed new renal scarring. This is attributable in part to the fact that the majority of patients (63–75%) with acute inflammatory changes on the initial DMSA renal scans did not have VUR. Nevertheless, in one prospective study of 38 kidneys with initially abnormal DMSA scans, scarring developed in 6 of 15 (40%) kidneys with associated VUR and in 10 of 23 (42%) kidneys without demonstrable reflux.[54] Similar findings have been observed by others.[331] These observations provide convincing clinical evidence that renal parenchymal infection, rather than VUR, is the prerequisite for acquired (postnatal) renal scarring. Once bacteria have invaded the renal parenchyma, the inflammatory response appears similar and the propensity for renal scarring is equally as great whether or not reflux is present.

Despite these findings, the importance of VUR (particularly grades III or higher) as a risk factor for renal scarring should not be discounted. Clearly, patients with moderate and severe reflux are much more likely to develop acute pyelonephritic damage than children with mild or no reflux.[53,332] Furthermore, although 62% of the kidneys with postpyelonephritic renal scarring in one study were drained by non-refluxing ureters, renal scarring was still significantly more common in those kidneys with grade III or higher VUR compared with kidneys with mild or no reflux.[331] Thus, the increased propensity for scarring in patients with higher grades of VUR is attributable in part to the increased risk of these kidneys for acute inflammatory damage at the time of the initial infection.[53,240,331] Coupled with this, reflux (pyelotubular backflow of urine from the pelvis into the collecting ducts) of infected urine or scarring of adjacent papillae may transform marginally competent, non-refluxing papillae into papillae that do reflux, thereby predisposing the kidney to greater pyelonephritic damage.[53,311] Indeed, in one study which attempted to quantitate the area of acute pyelonephritic parenchymal damage, the presence of grade ≥3 reflux was associated with a significantly greater frequency of kidneys demonstrating large defects (defined as >10% of the kidney demonstrating DMSA uptake <2 SD of the control kidney) when compared with kidneys with no vesicoureteral reflux ($p < 0.02$).[332] Thus, when present, moderate or severe reflux (grade ≥3) remains the most significant host risk factor for acute pyelonephritis and renal scarring.

Other risk factors for the development of renal scarring include associated bladder pathology, regardless of whether reflux is present. In one study, the frequency of new renal scarring was significantly higher in kidneys associated with overt bladder pathology compared with those with normal bladders (86% vs 32%; $p = 0.028$).[233] Marked bladder thickening and

trabeculation, suggesting either functional or anatomic bladder outlet obstruction, was present in 67% of the patients with bladder pathology who developed new scarring. Urodynamic evaluation of children with neuropathic bladders associated with spina bifida has demonstrated that increased intravesical pressure may lead to upper tract deterioration, with or without VUR.[333] Animal studies have also shown an increased propensity for renal scarring when infection and reflux occur in the presence of bladder outlet obstruction.[311]

Two studies have also analyzed the association of various clinical and bacteriologic parameters with the development of new renal scarring.[233,331] In both, children who developed new renal scars were actually older at the time of acute pyelonephritis, although the difference was statistically significant in only one.[330] An elevated WBC count at the time of the initial infection was not associated with renal scarring. When comparing those patients with and without new scarring, no significant differences were noted in race, gender, duration of fever, maximum temperature, or acute inflammatory signs (CRP, ESR) at the time of the acute pyelonephritic episode. *E. coli* was cultured from the urine of 88–95% of the patients in both studies. Interestingly, new scarring occurred in 33–41% of patients infected with *E. coli* compared with 100% of patients in both studies who were infected with other bacteria. In one study no significant association was found between bacterial virulence factors (hemolysin, colicin, P-fimbriae) and renal scarring, although colicin production was found almost twice as often in the bacteria isolated from patients with new renal scarring.[54] In a more recent report of 157 children evaluated with a DMSA renal scan 1 year following their first-time symptomatic UTI, children with high levels of CRP, high fever, and dilating VUR were 10 times more likely to have scarring than children with normal or slightly elevated CRP levels, no or mild fever, and no reflux.[275]

Sequelae of renal scarring

Hypertension

Renal scarring is reported to be a common cause of hypertension in children and young adults.[334–337] The risk of hypertension in patients with renal scarring varies, based on length of follow-up and severity of scarring. In follow-up studies of children with renal scarring, approximately 6–13% of children with scarring will develop hypertension.[22,187,337,338] In some cases, it may be associated with progressive renal insufficiency.[339] A recent report of an older cohort of 294 patients (mean age at presentation, 17.3 years) with reflux nephropathy noted that the risk of hypertension increased with age and length of follow-up.[340] Whereas 8.5% of these patients had hypertension at presentation, 38% became hypertensive later on (mean age 34.2 years). Hypertension was significantly more common in those with severe bilateral parenchymal scarring. Similarly, in another series 13% (11/83) of children with renal scarring were hypertensive at initial evaluation and another 17% (14/83) developed hypertension over the subsequent 4–20 years.[341]

The development of hypertension is clearly related to the severity of renal scarring and is more often observed in patients with a history of recurrent episodes of pyelonephritis associated with moderate or severe VUR.[187,339] The actual risk for hypertension in children with milder degrees of scarring is unknown, but is undoubtedly less. The etiology of hypertension associated with renal scarring is controversial. Some investigators report no evidence that the renin–angiotensin–aldosterone (RAS) system contributes;[342,343] others report that it does.[344–347] Despite these controversies, most would agree that the risk for hypertension in patients with severe renal scarring is significant, and long-term follow-up is mandatory, since hypertension may take 10–20 years to develop.

Renal insufficiency

The actual risk of renal insufficiency secondary to postpyelonephritic renal scarring is unknown. The annual incidence of new patients presenting with end-stage renal disease (ESRD) associated with 'reflux nephropathy' in Australia and New Zealand between 1985 and 1989 was 3.9 and 4.89 per million of the population, respectively.[348] Overall, this represented 7% of all new cases of ESRD commencing treatment during this time period, including 24% in the teenage group. In a more recent study of 102 patients with ESRD seen at a pediatric hospital over a 10-year period, only 3 had reflux nephropathy, including 1 patient with no history of UTI and 1 patient with a single, afebrile UTI.[349] Only 1 child with grade II–III bilateral reflux had a history of recurrent UTIs.

Studies have shown that the incidence of renal insufficiency in patients with postpyelonephritic renal scarring increases with age. The incidence of renal insufficiency in a report by Martinell et al of 30 adults who were diagnosed with severe renal scarring as children was 10%.[22] Another study of an older cohort of 294 patients (mean age at presentation 17.2 years)

with reflux nephropathy found a 2% incidence of renal insufficiency glomerular filtration rate (GFR) – defined as <40–69 ml/min – at presentation, that increased to 24% at last follow-up (mean age 34.2 years). The more extensive the renal scarring, the higher proportion with renal insufficiency.[339] Most patients (90–100%) with reflux nephropathy and ESRD have focal segmental glomerulosclerosis, almost always associated with proteinuria.[350–353]

Treatment

The obvious goals of treatment of UTI are symptomatic relief and prevention of new or progressive renal damage, especially in infants and young children who are at greatest risk for renal scarring. Initial treatment, ideally, should be based on in-vitro sensitivity studies. Frequently, such testing is not done or treatment is instituted before the results are available. Fortunately, because the common uropathogens are susceptible to multiple antibiotics and the response to antibiotics correlates best with urine levels that are usually more highly concentrated than serum level, high cure rates have been reported in most therapeutic trials.[354]

Asymptomatic bacteriuria

Treatment of true asymptomatic bacteriuria does not appear to be necessary if the urinary tract is otherwise normal.[355–357] The risk for pyelonephritis in infants and young girls with untreated asymptomatic bacteriuria is small, and many demonstrate spontaneous remission.[5,11] In a prospective follow-up of 50 infants with initial screening bacteriuria, 37 were followed for a minimum of 6 years.[358] Of the original 50, 2 infants developed pyelonephritis within 2 weeks after bacteriuria was diagnosed. In 45, bacteriuria was left untreated. Spontaneous clearance was observed in 36, while in 8 clearance followed treatment with antibiotics for respiratory infections. Recurrences of bacteriuria were observed in 10 of 50 children, of whom one had pyelonephritis. No child had more than one recurrence. Follow-up urography in 36 of 50 children after a median of 32 months showed no evidence of renal damage in any of them.

In contrast to infants with screening bacteriuria, treatment of school-age girls with asymptomatic bacteriuria is followed by high recurrence rates of up to 80%.[12] Most are caused by new strains, which may carry the risk of being more virulent.[359,360] In contrast, when left untreated, spontaneous changes of strain are uncommon.[361]

Several studies in the 1970s reported that non-treatment of asymptomatic bacteriuria was associated with normal growth of kidneys without the development of new scars provided the urinary tract initially appeared normal radiographically.[208,209,362,363] In a 4-year follow-up by the Cardiff–Oxford Bacteriuria Study Group in children 5–12 years of age with untreated covert bacteriuria, new or progressive renal scarring did not occur unless VUR was present.[209] Similarly, the presence of asymptomatic bacteriuria in the absence of VUR is not a risk factor for renal scarring in children with neuropathic bladders who perform clean intermittent catheterization.[301]

Hansson et al compared, retrospectively, treatment vs non-treatment of asymptomatic bacteriuria in older girls (median age 8 years) with pre-existent renal scarring.[361] Many also had mild grade I–II/V VUR. Of 21 girls who were given a short course of antibiotics, 17 acquired a new infection within a year including 7 with pyelonephritic recurrences. Of 23 girls treated with antibiotic prophylaxis for 2–3 years, one-half developed breakthrough infections, and recurrences after completion of long-term prophylaxis were as common as after short-term treatment. Overall, in girls who received short- or long-term antibiotic treatment, 14 patients developed 21 episodes of acute pyelonephritis during a total of 140 patient-years of observation. In contrast, ABU was left untreated in 29 girls for a total of 74 patient years of observation. Only one patient developed acute pyelonephritis.

Based on this information it is reasonable that true asymptomatic bacteriuria, particularly in older girls, be left untreated.[154,211] However, in the presence of VUR, the risks of non-treatment of asymptomatic bacteriuria have not been clearly established, particularly in infants and younger children. It should also be recognized that bladder dysfunction is commonly found in girls with so-called asymptomatic bacteriuria, including detrusor instability and incomplete emptying.[101] This explains in part the marked tendency for recurrent infection after treatment of asymptomatic bacteriuria with antibiotics alone. Treatment of the underlying voiding dysfunction is key to the successful long-term management of these patients.

Uncomplicated lower urinary tract infection

Agents that have been used successfully for acute, uncomplicated lower urinary infections include sulfonamides, trimethoprim–sulfamethoxazole (TMP-SMX), nitrofurantoin, trimethoprim, and oral cephalosporins

(see Appendix). Unfortunately, ampicillin and amoxicillin are used commonly by primary healthcare physicians. High intestinal levels of these two antibiotics often result in rapid development of resistant enteric organisms, which then become the reinfecting bacteria. The emergence of resistant strains to ampicillin or amoxicillin has limited its initial efficacy in treating urinary infections compared with other antibiotics.[364] Resistance rates to ampicillin–amoxicillin have been recently reported to be as high as 54% in children with their first documented symptomatic UTI.[365] This drawback of the synthetic penicillins has been diminished by the relatively recent combination of clavulanic acid with amoxicillin (Augmentin). Clavulanic acid inhibits the bacterial β-lactamase enzymes, which render the β-lactamic antibiotics ineffective. This combination has proved effective in eradication of UTIs in children, even when in-vitro susceptibility testing demonstrated resistance to amoxicillin alone.[366,367] However, ampicillin–clavulanic acid is associated with a high incidence of side effects, is expensive, and is no more effective than the usual drugs.

The fluoroquinolones have been shown to have a wide spectrum of activity that includes most Gram-positive and Gram-negative organisms, including *Pseudomonas aeruginosa* and *Proteus*.[368] These are bactericidal agents and are believed to work by inhibiting the essential bacterial enzyme deoxyribonucleic acid (DNA) gyrase, which is essential for DNA replication in bacterial cells.[369] Concern regarding adverse arthropathic effects, based on animal studies showing cartilage toxicity, has prevented its approval for use in children.[370] However, the same experimental toxic effects have been reported with all quinolones, including nalidixic acid, which is licensed for use and has been used in children for decades.[371] A retrospective match-controlled study of nalidixic acid in 11 children treated for 10–600 days with follow-up examination 3–12 years later did not reveal any differences in arthropathic adverse effects compared with controls.[372] Furthermore, clinical evidence of cartilage toxicity has not been reported in more than 100 children with cystic fibrosis treated with varying courses of high-dose ciprofloxacin.[373] Despite the lack of clinical evidence demonstrating cartilage toxicity in children, the use of fluoroquinolones in growing children generally should be avoided until definitive studies have been performed.

Duration of treatment

The optimal duration of treatment of acute uncomplicated lower UTIs in children is controversial. Recently, several randomized, controlled studies have been published reporting the efficacy of single-dose or short-course antimicrobial therapy in children. The potential advantages of short-course therapy include decreased costs, improved compliance, decreased antibiotic-related side effects, and decreased effect on the fecal flora.

In 1988, Moffatt and associates reported a methodologic analysis by four independent reviewers of 14 randomized, controlled trials of short-course antimicrobial therapy for uncomplicated lower UTIs in children. Short-course therapy varied in these 14 studies. Conventional therapy ranged from 7 to 10 days. In two trials, short-course therapy was less effective.[374] One study compared single-dose vs 10-day amoxicillin therapy, and one compared 1-day vs 10-day cefadroxil therapy.[375,376] The other 12 studies showed no difference in outcome. The authors concluded that there was insufficient evidence to recommend short-course therapy for UTIs in children.

In a more recent review article by Khan, the findings in 12 of these reports were re-evaluated by pooling the data on 320 infants and children.[377] He reported that single-dose therapy achieved an overall cure rate of 89% (63–100%), defined as a negative follow-up culture at 1 week and the lack of a subsequent recurrence with the same organism. However, the response varied with the antimicrobial agents. Intramuscular aminoglycosides, used in 178 (56%), achieved the highest cure rate (96%), followed by TMP–SMX or a sulfa drug (90%). The cure rate of amoxicillin was significantly less (75%; $p < 0.01$). Another large clinical study investigated single-dose vs multidose antibiotic therapy in 132 children with a culture-documented 'first-time' acute UTI. There was no difference in the bacteriologic cure rate for single-dose (93%) vs multidose regimens (96%), but recurrence rates at 10–12 days or 28–37 days after treatment were significantly higher in the single-dose group (20.5%) compared with the 3-day (5.6%) and 7-day (8%) groups.[378]

Two other studies have compared relatively short 3-day vs conventional 10-day courses of antibiotics for treatment of uncomplicated UTIs in children. In one prospective, randomized, open multicenter study of 264 girls 1–15 years old, similar results were observed when short-course treatment with either 3 days of sulfamethizole or pivmecillinam was compared with 10 days of sulfamethizole.[379] Specifically, there was no difference in the number of girls with no or insignificant growth on urine cultures after treatment, or in the recurrence-free interval after treatment among the

three groups. In another study of 110 children, no difference in initial cure or subsequent relapse rates was found in children treated with 3-day therapy vs 10 days using either co-trimoxazole or nitrofurantoin.[380]

Based on the available data, it appears reasonable to treat acute lower uncomplicated infections in children with a 'relatively' short 3-day course of antibiotics. However, young children with their first-time infection or those with febrile infections should then continue to receive low-dose antimicrobial prophylaxis until radiographic evaluation is completed.

Pyelonephritis

The child with suspected pyelonephritis requires a greater degree of assurance of immediate therapeutic success, since the degree of scarring and renal damage resulting from an infection may be influenced by the rapidity of effective therapy.[31,252,315,316,381] Oral medication can be initiated in older children who are not septic or vomiting, as long as good compliance is ensured. TMP–SMX can be anticipated to be effective in most cases. Cephalosporins are also a good choice for initial therapy in the febrile child who does not require parenteral therapy. New third-generation cephalosporins such as cefixime offer the advantage of once-daily dosing and have been shown to be as effective as twice-daily TMP–SMX.[382,383] Treatment can be changed to include less expensive agents when the antibiotic sensitivities become available.

Although most would concur with a 10–14 day course of antibiotic therapy for pyelonephritis, there is considerable controversy over the need for hospitalization and treatment with parenteral antibiotics vs outpatient therapy with oral drugs. In a recent survey of 445 general practitioners, 143 pediatricians, and 45 pediatric nephrologists, there were significant differences in the recommendation for initial hospitalization by the general practitioners and pediatricians (17%) compared with the pediatric nephrologists (69%).[384] The pediatric nephrologists were evenly split between single and combined antibiotic therapy, whereas general practitioners and pediatricians preferred monotherapy. Intravenous antibiotics were preferred by 78% of the pediatric nephrologists compared with only 23–27% of pediatricians and general practitioners. This may suggest a greater concern and/or awareness on the part of the nephrologists regarding the potential for renal damage associated with pyelonephritis in children. However, in a recent prospective randomized clinical trial of 306 children 1–24 months old with febrile UTIs, outpatient treatment with oral third-generation cephalosporins was equally effective when compared with initial treatment with intravenous antibiotics. There was no significant difference in treatment success, duration of fever, or subsequent renal scarring on DMSA scans.[383]

Clearly, there is a need for controlled therapeutic trials for UTI in children with old and new drugs in different dosages and for varying lengths of treatment. These trials should categorize patients into different age groups such as: (1) neonates aged 0–28 days; (2) infants aged 1 month to <2 years; (3) older children ≥2 years; and (4) adolescents.[385] Meanwhile, until such clinical trials are conducted, non-toxic children and infants >3 months of age can be treated as outpatients as long as compliance is not an issue. It is reasonable to initiate therapy with 1–2 days of a long-acting, third-generation cephalosporin, such as ceftriaxone, administered intramuscularly, followed by 10–14 days of oral antibiotics and prophylaxis until evaluated. Ceftriaxone is active against most Gram-negative uropathogens and it achieves very high levels in both the urine and renal parenchyma following single daily doses. This approach virtually assures compliance and adequate antimicrobial coverage until the urine culture and sensitivity results are known. Alternatively, if compliance does not seem to be a problem, initial therapy with appropriate, broad-spectrum oral antibiotics may be as effective in the treatment of acute pyelonephritis and in the prevention of irreversible renal damage.[383]

In contrast, the toxic child and infants <3 months of age with suspected acute pyelonephritis should be considered candidates for immediate hospitalization and parenteral therapy. In these patients combination therapy, including an aminoglycoside and ampicillin, are appropriate choices until the urine culture results are known. Alternatively, one of the newer third-generation cephalosporins may be used, but these are more expensive and do not provide comprehensive coverage of Gram-positive organisms, including *Enterococcus*. Parenteral antibiotic therapy should be continued for 7–10 days in neonates, although oral outpatient therapy to complete a full 10–14 day course can be substituted in patients >2 months when afebrile for 24–48 hours. Follow-up specimens for urine culture should be obtained at the completion of therapy, and prophylaxis should be instituted until evaluation of the urinary tract is completed.

Prophylaxis

Long-term, continuous antibiotic prophylaxis is recommended in children with VUR (particularly under

8 years of age) and those with frequent symptomatic recurrences. Antibiotic prophylaxis should also be considered in young children (under age 1) with non-reflux acute pyelonephritis when acute or chronic renal damage is documented by cortical scintigraphy. These children, in particular, appear to have bacterial virulence–host defense factors that appear to place them at significant risk for pyelonephritic damage.

In children with VUR, prophylaxis is usually continued until the reflux spontaneously resolves or is surgically corrected. Some advocate stopping prophylaxis in children older than 7 or 8 years of age who have mild or even moderate (grades I–III) VUR, particularly when there is no evidence of prior renal scarring.[386] If infection recurs during that time and reflux persists, correction shoud be considered for those with clinical or DMSA scan-documented pyelonephritis. Regardless of whether reflux is present, girls with a history of recurrent UTIs should be advised of the importance of surveillance urine cultures during pregnancy because they are at increased risk for pyelonephritis. In one review, a group of 41 women who had UTIs in childhood were followed through 65 pregnancies.[21] They were compared with age-matched controls. Of those with a history of childhood UTIs, 19 had renal scarring and 22 did not. The incidence of bacteriuria was higher in those with renal scarring (47%) than in those without renal scarring (27%), but both were significantly greater ($p < 0.001$ and $p < 0.01$, respectively) than in controls without a history of UTI (2%). This is true regardless of whether or not reflux is present.[20] Even those who underwent successful surgical correction of reflux during childhood continue to be at increased risk for pyelonephritis during pregnancy.[387–389]

Children with recurrent pyelonephritis and those with frequent recurrent symptomatic lower UTIs (three in 6 months, four in a year) should also be considered for prophylaxis for a minimum of 6–12 months, even in the absence of VUR. Periodic urine specimens for culture should be obtained every 3–6 months to monitor the success of prophylaxis. Medication should then be reinstituted for an additional 12 months if infection recurs within 3 months of discontinuation. It is not necessary to discontinue treatment to obtain urine specimens for culture. When breakthrough infection occurs, the offending organism will be resistant to the current agent. Therefore, the culture media will not be sterilized by the excreted drugs.

Although prophylaxis effectively prevents infection, it cannot be expected to reduce the recurrence rate of urinary infection after therapy has been discontinued. In one trial using TMP–SMX, all the children were treated for 2 weeks and then were randomized to receive no treatment or 6 months of prophylaxis.[390] Although prophylaxis was highly effective in preventing infection, the rate of recurrent infection after stopping prophylaxis was virtually identical to that observed after 2 weeks of treatment. Similarly, Smellie et al reported a high recurrence rate (42%) in children with a history of recurrent urinary infections following discontinuation of long-term antimicrobial prophylaxis.[180] In those with cystitis cystica (cystitis follicularis), 80% experience recurrences within 1 year after 6–12 months of continuous prophylaxis.[391] Nevertheless, it is helpful to achieve an infection-free period in those children with a history of multiple, symptomatic urinary infections. During this period of time, aggressive efforts should be made to improve the voiding and bowel habit patterns in those children who have clinical and/or urodynamic evidence of dysfunctional voiding, a common finding in this difficult group of patients.

Antimicrobials with proven efficacy in the prevention of recurrent urinary infections include nitrofurantoin, TMP–SMX or TMP–sulfadiazine, and TMP alone.[180,357,392–394] In one study that compared prophylaxis with nitrofurantoin vs trimethoprim alone in a double-blind study in 130 children, nitrofurantoin demonstrated superior efficacy in those chldren with abnormal urography and/or reflux.[395] However, no differences were seen in children without urinary tract abnormalities. Nitrofurantoin did not alter the pattern of resistance of intestinal bacterial flora, whereas trimethoprim significantly increased the percentage of trimethoprim-resistant bacteria during prophylaxis. Side effects, primarily gastrointesinal, were more frequent in the nitrofurantoin group (37%) compared with the trimethoprim group (21%) ($p = 0.05$). The authors recommended nitrofurantoin as the first choice for prophylaxis in children with recurrent UTI and urinary tract abnormalities. Pure SMX is less effective, and synthetic penicillins are particularly poor prophylactic agents because of the frequent emergence of resistant organisms.

Prophylactic doses are generally less than those used to treat acute infection. Smellie et al effectively used SMX 10 mg + TMP 2 mg/kg/day, or nitrofurantoin 1–2 mg/kg/day in one to two doses.[391,392] Our practice is to administer one-third to one-half of the therapeutic dose once daily. Alternatively, intermittent prophylaxis with low-dose TMP–SMX every other day has also been reported to be effective both

in children with VUR and preadolescent girls with recurrent infection.[396,397] In difficult cases of children who develop breakthrough UTIs on single-drug antimicrobial prophylaxis, double prophylaxis with nitrofurantoin and TMP–SMX has been shown to be effective in reducing recurrences. In one study of 31 girls with recurrent breakthrough infections on single-drug therapy, 68% had VUR, 49% had voiding dysfunction, and 26% had both.[398] When treated with double drug prophylaxis, the rate of infection was reduced from 17.4 UTIs/100 patient-months to 3.6 UTIs/100 patient-months (p <0.001). These patients were also treated with anticholinergics and frequent timed voiding.

Renal abscess

In the past the majority of renal abscesses, a rare form of renal infection, were not caused by ascending infection. Historically, *Staphylococcus aureus* has been the offending agent as a result of hematogenous seeding from a peripheral cutaneous site of origin, or seeding of the contused renal parenchyma after blunt abdominal trauma.[399,400] Diagnosis is often delayed in these patients because urine cultures are negative in most. With the advent of early recognition and effective therapy, the frequency of staphylococcal bacteremia and renal abscesses has decreased. More cases of Gram-negative infections in the presence of VUR or other anatomic abnormalities of the urinary tract are now being seen.[401]

Most patients with a renal abscess present with high fever, leukocytosis, and an elevated ESR, often accompanied by flank pain. A variety of imaging techniques have been used to diagnose renal abscesses, including IVP and angiography, gallium-67 scintigraphy, sonography and CT[402–405] (Figure 7.28). The classic treatment of renal abscess has been surgical drainage in addition to appropriate antibiotic therapy. However, improved antibiotics and diagnostic techniques, together with the ability to obtain culture by percutaneous aspiration or drainage under ultrasonic control, have often obviated the necessity for surgical intervention. In 7 patients reported by Schiff et al, 10

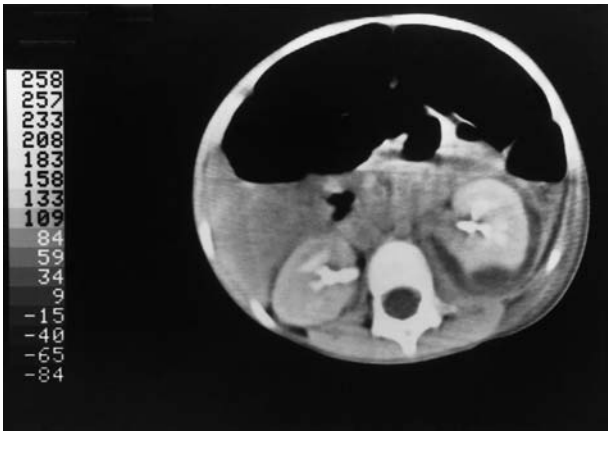

Figure 7.28 CT scan reveals a filling defect in upper pole of left kidney consistent with a renal abscess in a child with flank pain and fever. (Reprinted from Rushton,[297] with permission.)

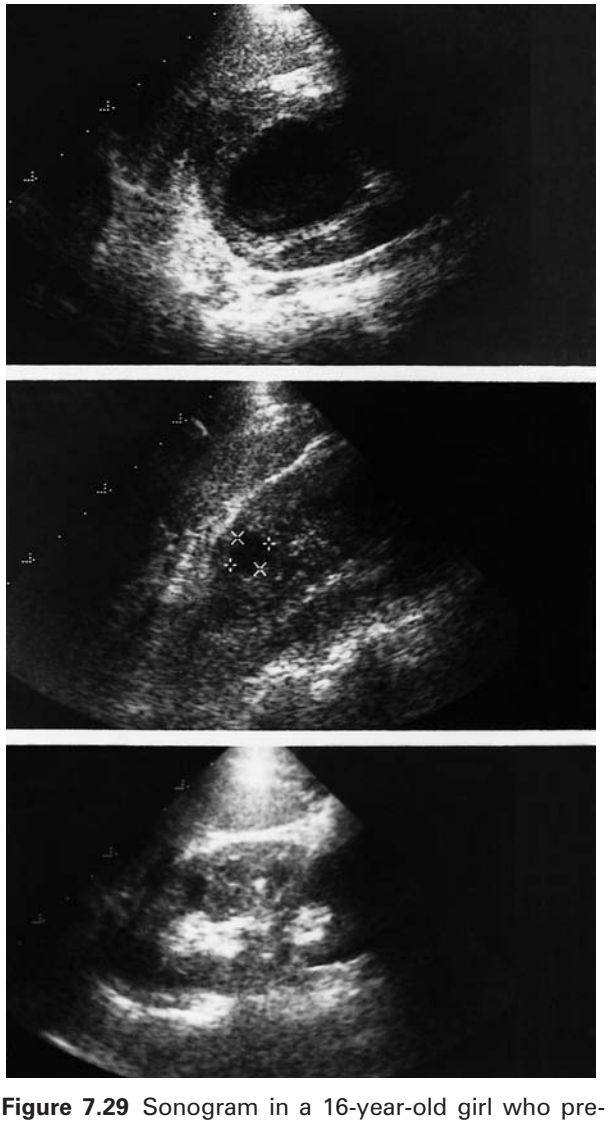

Figure 7.29 Sonogram in a 16-year-old girl who presented with fever and flank pain. (*Top*) Sonolucent mass in the left upper pole consistent with a renal abscess. Needle aspiration under sonographic guidance yielded purulent material that grew *E. coli.* Following 2 weeks of parenteral and 4 weeks of oral antibiotic therapy, sonograms 7 weeks later (*middle*) and 17 weeks later (*bottom*) show progressive resolution of abscess cavity. (Reprinted from Rushton,[297] with permission.)

days of parenteral antibiotic treatment alone followed by an additional 2 weeks of appropriate oral therapy was successful.[406] However, in a review of the literature performed by Steele et al, 62% (16/26) of the children with renal abscesses ultimately required surgical intervention.[407] Unfortunately, no controlled data exist that rigorously compare the resolution rate between children treated with antibiotics alone vs those treated with antibiotics and drainage. Currently, most cases of renal abscess initially can be managed without intervention, percutaneous drainage being reserved for persistent infection (Figure 7.29). Children who are immunocompromised by virtue of malnutrition or infection with the human immunodeficiency virus (HIV) are at particular risk for developing recurrent renal abscesses and abscesses containing unusual organisms (*Listeria monocytogenes*).[408,409] In these circumstances, more aggressive surgical or percutaneous intervention is often necessary early to eradicate the infection.

Treatment in renal failure

The dynamics of antibiotic detoxification and excretion are usually deranged in the child with renal failure. Antibacterial doses need to be adjusted in such patients to avoid adverse reactions. Certain drugs – those that are dependent on renal function for efficacy – are useless in these patients. The frequency of administration of those drugs that are effective in the face of renal failure – rather than their dosages – should be modified based on the degree of renal insufficiency.

Dysfunctional elimination

In addition to appropriate antimicrobial therapy, other factors must be taken into consideration in patient management. Voiding frequency and control of constipation are the two most common variables that are readily changeable and may be the most important in effecting changes in susceptibility to infection, particularly for children who are infrequent voiders. Establishing a voiding schedule in children may be extremely difficult and may provoke conflict in the parent–child relationship. The physician can interject his influence by explaining the treatment goal to the child and requesting that a regular voiding pattern be instituted and maintained. Children should be told that they will be reminded by their parents to void regularly and that they should follow this request even if they do not feel the urge to void at that time. Multialarm wrist watches can be a useful and inexpensive reminder for older school-age children.

The mainstay of treatment of children with recurrent UTIs and underlying bladder instability involves the long-term use of anticholinergic medicine, primarily oxybutynin (Ditropan). Other anticholinergic and antispasmodic agents include hyoscyamine (Levsinex) and tolterodine (Detrol). Koff et al reported that after initial clearing of urinary infection, 31 of 58 (58%) children with recurrent UTIs and uninhibited bladder contractions who were treated with anticholinergics alone maintained sterile urine. The necessity for long-term antibiotic prophylaxis in these patients is then determined by the frequency of subsequent recurrences and/or the presence of VUR.[103] For children older than 6 years, the usual dosage of oxybutynin is 2.5–5 mg, given two to three times daily. A new long-acting formulation, Ditropan XL, is now available which only requires once-daily dosing. The usual dose for hyoscyamine in this age group is one 0.375 mg cap twice daily. Although not yet approved for children, tolterodine has been used successfully with doses of 1–2 mg twice daily. Reportedly, tolterodine has a more specific action on the bladder and is associated with fewer side effects. Comparative efficacy among these medications has not been established in children. Timed voidings should always be used in conjunction with anticholinergic therapy.

In more difficult cases of voiding dysfunction with detrusor–sphincter dyssynergia, pelvic floor relaxation biofeedback therapy has been used successfully in the treatment of recurrent UTIs.[410] In a recent report, 42 girls with recurrent UTIs and urodynamically confirmed dysfunctional voiding were treated with a multimodal approach involving pelvic floor relaxation biofeedback, a voiding and drinking schedule, anticholinergics in those with bladder instability, and antibiotic prophylaxis.[112] This combined therapeutic approach was effective in preventing recurrent UTIs in 35 (83%).

For constipation, an intensive therapeutic approach is often required. Initially, in severe cases, enemas given for several days may be necessary to disrupt a high fecal impaction and relax an overstretched colon. Increased intake of fiber and fluid and regular toilet habits must then be instituted. In refractory cases, regular use of a fiber-based laxative may be necessary. In most cases, these are long-term requirements, and failure to continue this regimen generally results in recurrence of both constipation and UTI.[411] A recent study of 234 constipated and encopretic children found that urinary infection was present in 11%, daytime urinary incontinence in 29%, and nocturnal

incontinence in 34%.[111] During follow-up of at least 12 months after initiation of treatment for constipation, recurrent UTIs were effectively prevented in all patients who had no anatomic abnormality of the urinary tract. Daytime urinary incontinence resolved in 89% and nocturnal incontinence resolved in 63% of patients.

Urinary stasis for any other reason needs to be addressed if infection cannot be otherwise controlled with antibiotic prophylaxis. Causes may include severe reflux with secondary poor bladder emptying (megacystis–megaureter syndrome), dilatation in the absence of obstruction, bladder diverticula, or residual ureteral stumps. Since otherwise unexplained urinary infection is so common, it is incumbent upon the physician to document the influence of any of these entities on infection prior to recommending surgical correction. For example, a specimen for culture may be obtained by needle aspiration of a dilated, non-obstructed upper collecting system to ascertain its involvement prior to surgical revision.

Tuberculosis

The advent of effective antituberculous agents has made genitourinary tuberculosis an uncommon occurrence in the Western world. In 1984, 21 197 cases were reported in the United States and nearly 2000 people died of the disease.[412] The infection rate in children living in the United States whose parents were born there ranges between one and two cases per 10 000 per year. Genitourinary tuberculosis accounts for approximately one-fifth of the cases of extrapulmonary tuberculosis.[412]

Tuberculosis in children occurs most often in lower socioeconomic groups. Case rates are higher in black children and other minorities than in white children. Transmission of tuberculous infection from mother to infant via the placenta or amniotic fluid has been reported in 130–200 patients.[413]

Pathogenesis

Mycobacterium tuberculosis, the tubercle bacillus, is a slow-growing, acid-fast organism that is usually acquired through inhalation of respiratory droplets from an infected person. Renal tuberculosis is always preceded by a focus of infection in some other organ system, usually pulmonary.[414] The tubercle bacilli gain access to the kidneys by means of hematogenous dissemination, and therefore renal infection must be considered bilateral in nature.

Pathology

Genitourinary tuberculosis occurs in 4–15% of patients with tuberculosis;[415,416] it accounts for 73% of the cases of extrapulmonary tuberculosis.[417] Renal tuberculosis is a late and uncommon complication of pulmonary disease, and occurs less than 4–5 years after primary infection. Predisposing conditions, such as malnutrition, diabetes mellitus, and chronic corticosteroid administration play a significant role in the development of genitourinary tuberculosis. Like all blood-borne renal infections, the tuberculosis bacillary emboli are deposited initially in the glomerular and cortical arterioles and cause small tubercles to develop. These tubercles undergo necrosis, with eventual caseation and cavitation of sloughed material into the caliceal walls at the papillary tips. The lesions may extend throughout the renal parenchyma and cause total destruction of the renal pyramids. Rupture of the bacilli into the calyx and collecting system results in extension of disease to other calices, renal pelvis, ureter, and bladder.

Local progression results in fibrosis causing stenosis of the caliceal neck, infundibulum, ureteropelvic junction, mid-ureter, and ureterovesical junction. Ureteral fibrosis results in straightening and shortening of the ureter and ultimately produces the classic gaping ureteral orifice with vesicoureteral reflux. Alternatively, ureteral stricture may produce hydroureteronephrosis and ultimately non-functioning 'autonephrectomized' kidney.[418] Involvement of the bladder by tubercle bacilli causes ulceration and bleeding with destruction of the vesical mucosa.

Tuberculosis of the genital tract is uncommon in both sexes before puberty. In males, involvement of the genital tract usually occurs either hematogenously or through retrograde passage of infected urine through the posterior urethra in the prostatic ducts. Tuberculous epididymitis or epididymo-orchitis can occur in early childhood and may be the initial method of presentation. The fallopian tubes are involved in approximately 90%, the endometrium in 50%, the ovaries in 20–30% and the cervix in 2–4% of females with genital tuberculosis.[413]

Symptoms

The majority of children with genitourinary tuberculosis have no symptoms during the initial infection.[419] Due to the lagtime between pulmonary infection and the clinical onset of renal tuberculosis, symptoms of frequency, dysuria, hematuria, and pyuria occur late in the course of disease, when the lesions ulcerate

through the calices and renal pelvis, and tubercle bacilli are disseminated to the bladder. Genitourinary tuberculosis must be suspected in children with sterile pyuria, draining sinuses, and those with a history of tuberculosis elsewhere in the body. One child with a tuberculous vesicovaginal fistula and total urinary incontinence has been reported.[420] With treatment of the tuberculosis, the fistula closed and the incontinence was corrected.

Diagnosis

Microscopic hematuria and pyuria are usually present. Routine urine specimens for culture are often negative; however, 15–20% of patients with tuberculous bacilluria may have coexistent bacterial infection. The diagnosis of genitourinary tuberculosis is suggested by the demonstration of acid-fast bacilli in the stained urinary sediment and is confirmed by culture, usually guinea pig inoculation. Collection of fresh morning urine specimens appears to be just as accurate as 24-hour urinary concentrates in providing the diagnosis.[421] The acid-fast tubercle bacilli are discharged intermittently, and therefore at least three separate specimens should be collected for study. Tetracycline and sulfa medications exert mild bacteriostatic effects on tuberculosis cultures, and these drugs should be discontinued before urine collection.[422] Skin tests for tuberculosis (PPD) are usually positive except in cases of overwhelming infection, or with human immunodeficiency virus (HIV) infection. The erythrocyte sedimentation rate (ESR) may be increased, and anemia may be seen in advanced disease.

Plain films of the abdomen may reveal punctate calcification overlying the renal parenchyma.[423] In approximately 10% of patients with renal tuberculosis, calculi are present. The earliest radiographic findings on the excretory urogram are minimal caliceal dilatation or erosion of the papillary tip. As the infection proceeds, there is increased destruction of the calices. With advanced disease, there may be cavitation and cicatricial deformity of the collecting system, progressing to pyonephrosis and non-function. Conversely, a normal excretory urogram does not rule out active genitourinary tuberculosis. In patients with hydroureteronephrosis or non-functioning renal units, ureteral catheterization may be helpful for selective urinary collection and retrograde pyelography may be necessary to provide accurate delineation of pyelocaliceal architecture.

Cystoscopic examination reveals only minimal inflammatory changes in the early stages of disease. With coalescence of the tubercles, there may be areas of white or yellow raised nodules with a halo of hyperemia. With advanced localized disease, bladder capacity may become markedly diminished, with fixed and incompetent ureteral orifices, mucosal ulceration and diffuse cystitis.

Treatment

The advent of short-course chemotherapy has changed the surgical management of genitourinary tuberculosis.[424] The current recommendation is for surgery to restore function or to remove irreparable disease. Surgery can be performed 6 weeks after the start of chemotherapy.

Antituberculosis drugs inhibit multiplication of tubercle bacilli and arrest the course of disease progression. Various antituberculosis agents are currently available.[413,425,426] The efficacy of combination chemotherapy compared with single-drug administration has been well documented and treatment with orally administered agents is as effective as parenteral drug administration.

Isoniazid

The dosage of isoniazid (INH) is 10–20 mg/kg of body weight per day, up to 300 mg daily, given in one dose. The drug is the most effective of the antituberculosis agents available and remains the keystone of all therapeutic regimens. Isoniazid is metabolized in the liver and is excreted primarily through the kidney. It is available in liquid form (50 mg/5 ml) and in tablets, which may be dissolved in fruit juice or water; this makes drug administration easier in infants and young children. Peripheral neuritis is the most common side effect and is probably caused by inhibition of pyridoxine metabolism. Neurotoxic side effects have not been reported in children younger than 11 years of age, and thus pyridoxine supplementation is not recommended unless nutrition is inadequate. Hepatotoxicity, which is seen often in older patients, rarely occurs in children.

Rifampin

The dosage of rifampin is 10–20 mg/kg/day, up to 600 mg daily. Rifampin is extremely effective and virtually non-toxic for administration in children. Rare cases of minor hepatic and renal dysfunction and thrombocytopenia have been reported. This drug is indicated for the initial treatment of genitourinary tuberculosis and for cases requiring re-treatment.

Rifampin is excreted in the bile and urine and may cause orange discoloration of urine, tears and sweat. In older females taking rifampin, contraceptive drugs should be avoided because rifampin changes the kinetics of the estrogen component.

Ethambutol

The dosage of ethambutol is 15–20 mg/kg/day, up to 2500 mg daily, divided into two to three doses. This is an extremely effective antituberculosis drug, which has replaced *p*-aminosalicylic acid for use in most adults. It is rapidly absorbed and excreted in the urine. Optic neuritis is a major toxic effect of ethambutol, and monthly visual examinations are required. This drug is not recommended for use in small children who are not able to cooperate in examination of visual acuity and color vision.

Streptomycin

The dosage of streptomycin is 20–40 mg/kg/day given intramuscularly, up to 1000 mg daily. Although streptomycin is still a useful drug for the treatment of genitourinary tuberculosis, the risk of eighth nerve damage prohibits use of this medication for longer than 12 weeks.

p-Aminosalicylic acid (PAS)

The dosage of PAAS is 200 mg/kg/day, up to 10 g daily. PAS is an effective bactericidal drug for the treatment of renal tuberculosis when used in combination with other antituberculosis medications. However, PAS is not effective when used alone. Major side effects are gastrointestinal problems, including nausea, vomiting, diarrhea, and anorexia. It is best to give PAS after meals and in the form of sodium and potassium PAS to decrease gastrointestinal irritability.

Pyrazinamide

The dosage of pyrazinamide is 30 mg/kg/day, up to 2 g/day. The drug is bactericidal, seldom hepatotoxic and well tolerated by children.

Ethionamide

The dosage of ethionamide is 15–20 mg/kg/day, up to a maximum of 1 g/day. The drug is well tolerated by children, is bacteriostatic, and occasionally is useful for drug-resistant cases. A physician experienced with this drug should be consulted prior to its use.

Other drugs

Cycloserine, kanamycin, and capreomycin may be useful in treating drug-resistant cases of genitourinary tuberculosis.

Specific therapy for genitourinary tuberculosis

The accepted treatment for genitourinary tuberculosis is triple-drug chemotherapy administered daily for 2 years.[427] Short-course chemotherapy (6 month treatment regimen) has been advocated in an attempt to (1) increase patient compliance, (2) decrease the cost of medication, (3) lower drug toxicity, and (4) produce an equally successful regimen comparable with the standard therapy.[424,428] Short-course chemotherapy must include rifampin as one of the drugs.[412]

The recommendation of the American Academy of Pediatrics for treatment of genitourinary tuberculosis is 9 months of INH and rifampin. In the first 2 months of therapy, a third drug should be added. This may include pyrazinamide, streptomycin, or ethambutol in children older than 5 years of age. If the infection is associated with HIV infection, treatment should include three drugs and may need to be longer than 9 months.[425]

The majority of relapses occur within the first 2 years. Females in the childbearing years should avoid pregnancy until therapy is completed.[429] Women who are delivered of a baby while they have genitourinary tuberculosis may infect the infant with tuberculosis.[430]

With the rapid bactericidal activity of drugs like rifampin, recent recommendations call for 1-year follow-up unless calcification is seen on abdominal radiographs.[412] If calcification is present, long-term follow-up is required to be sure that the disease does not progress. During the follow-up period, urinalysis is performed every 2 months. The upper urinary tracts should be monitored prior to, during, and after treatment to assess for obstruction because strictures are common.

Surgical therapy in patients with genitourinary tuberculosis is essentially of historical significance.[431,432] The result of chemotherapy are so impressive that surgical intervention is limited to exceptional cases such as ureteral stricture,[418] ureterovesical junction reconstruction, or augmentation cystoplasty in children with small contracted bladders.[433]

Xanthogranulomatous pyelonephritis

Xanthogranulomatous pyelonephritis is an atypical form of severe chronic renal parenchymal infection characterized by unilateral destruction of parenchyma

and accumulation of lipid-laden macrophages (xanthoma cells) either surrounding abscess cavities or as discrete yellow nodules. More than 50 cases of xanthogranulomatous pyelonephritis have been reported in children.[434–436] The age of presentation has ranged from infancy to 16 years. Most patients present with non-specific symptoms of chronic infection, including weight loss, recurrent fever, failure to thrive, pallor, and lethargy, although those with the focal form often appear healthy.[434,435] A palpable abdominal mass is present in approximately one-third of cases. Bacterial specimens for culture can be obtained from the urine or renal abscess in the majority of cases, with *Proteus* being the most common organism isolated.

Both diffuse and focal forms of the disease have been reported, with the focal form being more common in children than in adults.[435,437] The pathologic and radiologic differences between focal and diffuse xanthogranulomatous pyelonephritis have been described.[438] Radiologic evaluation in the diffuse form of the disease often reveals non-function of the entire kidney. Calcification or stones may be present, although this is less common in the focal form of the disease. Characteristic sonographic or CT appearances of xanthogranulomatous pyelonephritis have also been reported.[439] However, these features are non-specific and often mimic neoplasia or other forms of chronic inflammatory renal parenchymal disease. Consequently, the correct diagnosis is seldom made preoperatively. Nephrectomy is curative, although partial nephrectomy may be adequate in focal disease, assuming that the diagnosis can be established. No incidence of recurrence in the contralateral kidney has been reported.

Appendix: antibacterial agents

Sulfonamides

Sulfonamides act by competitively blocking the conversion of para-aminobenzoic acid to folic acid.[422] About 75% of the oral dose is absorbed. Free sulfonamide is excreted into urine by filtration and tubular secretion. Although high tissue levels are not achieved, excellent urine levels result. Sulfonamides are most effective against *E. coli* but also may be effective against other Gram-negative and Gram-positive organisms.

Sulfonamides are well tolerated by children, are inexpensive, and produce few side effects. They affect the gastrointestinal flora when used for long-term prophylaxis but are effective agents for short-term acute therapy of uncomplicated infections. They displace protein-bound bilirubin and hence in the neonate have the potential to interfere with bilirubin excretion and cause jaundice. Once the infant has passed through the period of 'physiologic jaundice,' these agents can be utilized safely. Some patients are allergic to sulfa drugs, but fortunately most reactions are of a minor cutaneous nature, such as urticaria. There have been some problems with major hypersensitivity reactions, such as the Stevens–Johnson syndrome, but these are rare. The most widely used agent is sulfisoxazole, employed in a dose of 120–150 mg/kg of body weight per day, given acutely in four to six divided doses orally.[441,442]

Trimethoprim–sulfamethoxazole

The TMP–SMX combination is useful both in the management of simple cystitis and for long-term antibacterial prophylaxis. This combination has a diminished effect on bowel flora and offers the advantage of trimethoprim entering vaginal secretions in the adult female.[443] This latter characteristic appears to be of particular utility in its effectiveness as a prophylactic agent. In addition, trimethoprim has also been shown in vitro to induce phase variation of fimbriated *E. coli* to a non-fimbriated state.[444] This and the high concentration in vaginal secretions work to prevent vaginal and periurethral colonization with organisms that could potentially cause urinary tract infection. Trimethoprim interferes with dihydrofolic acid reductase, and sulfa methoxazole blocks the conversion of para-aminobenzoic acid to dihydrofolic acid. The combination is effective against many Gram-negative as well as Gram-positive organisms. It is well absorbed, attains high levels in both serum and urine, and is well tolerated by children. Neutropenia and thrombocytopenia are not uncommon with its use. However, the significance of these changes is unknown.[445]

The combination is available as a suspension containing 40 mg of trimethoprim and 200 mg of sulfamethoxazole per 5 ml. The dose employed in children over 2 months of age is TMP 6–12 mg and SMX 30–60 mg/kg/day, in two divided doses.[441]

Nitrofurantoin

Nitrofurantoin is quite useful in the treatment of simple cystitis and is also a very effective agent for long-term, low-dose prophylaxis. It is thought to interfere with early stages of the bacterial Krebs cycle.[442] It is well absorbed from the gastrointestinal tract and has minimal effect on bowel flora. Tissue levels are low because it is excreted almost entirely in the urine by glomerular filtration. Urinary levels tend

to be quite high. Urinary alkalinization increases urine levels, whereas acidification increases tissue levels. It works well against most *E. coli* and enterococci but is not particularly effective against *Klebsiella, Proteus,* or *Pseudomonas*.

Nausea and vomiting are frequent troublesome side effects in children; however, these can be minimized by administering the agent immediately following a meal or by utilizing nitrofurantoin macrocrystals supplied in capsule form. For the small child, the contents of the capsule can be emptied and administered in potatoes or apple sauce.

In neonates, nitrofurantoin has the potential to cause a hemolytic anemia because of glutathione instability. Consequently, it should not be used in this age group. Additionally, the drug is ineffective in patients with significant renal impairment. Other side effects are rare but do include peripheral neuropathy and pulmonary infiltrates. The usual dose in children older than 3 months of age is 5–7 mg/kg/day given orally in three to four divided doses.[441]

Penicillin

The penicillins as a class are probably the most widely used antibiotics. All act by blocking mucopeptide synthesis in the cell walls so that the bacterium is unprotected from its high internal osmotic pressure. This effect occurs only in growing cells.

Penicillin G

Extremely high urine levels can be achieved with penicillin G in patients with normal renal function, and under these circumstances this drug may be very effective against both *E. coli* and *Proteus*. Its major toxic effect is allergy manifested by rash or anaphylaxis.

Ampicillin

Ampicillin is the most widely used penicillin in the treatment of UTIs. It is not well absorbed from the gastrointestinal tract; therefore, high fecal levels do occur and diarrhea is common. High serum and urine concentrations are achievable. This agent should not be administered to patients with a known history of penicillin allergy. The usual dose is 50–100 mg/kg/day given every 6 hours. It can be administered either orally or intravenously.[442]

Amoxicillin

Amoxicillin is a derivative of ampicillin that is absorbed more readily and therefore produces less diarrhea. It is administered orally in a dose of 20–40 mg/kg/day every 6–8 hours.[442]

Carbenicillin

Carbenicillin is an agent that may be useful in the treatment of *Pseudomonas* and indole-positive *Proteus*; however, its usefulness is often diminished by the emergence of resistant strains. It is available as tablets and as a parenteral solution. When it is used parenterally for UTI in children, the usual dose is 50–200 mg/kg/day given every 4 hours; for severe infections, the dose can be increased to 400–500 mg/kg/day.[446] The oral form is not predictably effective in children.

Ticarcillin

Ticarcillin is available for parenteral therapy only. Like carbenicillin, it is active against *Pseudomonas* and indole-positive *Proteus*, which may be resistant to other drugs. It is often used with an aminoglycoside for a synergistic effect. This combination may also delay the emergence of resistant strains. Sodium overload is less likely to occur with ticarcillin compared with carbenicillin. The usual dose in children for treatment of UTI is 50–100 mg/kg/day given every 4–6 hours. In life-threatening infections, the dose can be increased to 200–300 mg/kg/day.[446]

Piperacillin

Piperacillin has essentially the same antimicrobial spectrum as carbenicillin and ticarcillin, but is more effective on a weight basis. Piperacillin may have some advantage in allowing lower doses and therefore less sodium load compared with carbenicillin and ticarcillin. The dosage in children is 50 mg/kg/day given every 4–6 hours.[426]

Cephalosporins

Cephalosporins are usually effective against most of the Gram-negative and many of the Gram-positive pathogens. Excretion is by both glomerular filtration and tubular secretion. Although there can be some cross-reactivity in patients who are allergic to penicillin, in general these agents can be cautiously administered to patients with penicillin allergy.

Oral drugs

Oral cephalexin, a 'first-generation' cephalosporin, is well absorbed from the gastrointestinal tract, and can be given in a dose of 25–50 mg/kg/day every 6 hours.[441]

Cefaclor, a 'second-generation' oral cephalosporin, is somewhat more active against Gram-negative bacteria but is more expensive than cephalexin. The dosage is 20–40 mg/kg/day given every 8 hours.[441] Other oral cephalosporins include cephradine (first generation) and cefadroxil (second generation). A new 'third-generation' cephalosporin for oral administration, cefixime, is now available. In addition to broader coverage of Gram-negative organisms, an advantage of cefixime is a prolonged half-life, allowing for once- or twice-daily dosage. The recommended dose for children is 8 mg/kg/day in one or two divided doses.[447]

Parenteral drugs

Numerous cephalosporins are available for parenteral use. The first-generation cephalosporins (cephalothin, cefazolin, cepharadine, cephapirin) are useful agents for urinary infections caused by most strains of *E. coli, Klebsiella*, and *Proteus*, but not *Pseudomonas*. As with all cephalosporins, they are inactive against enterococci. The second-generation parenteral cephalosporins (cefamandole, cefoxitin) are more active than the first-generation agents against many enteric Gram-negative bacteria, but not *Pseudomonas*. Cefoxitin is the most active cephalosporin against anaerobes, including *Bacteroides fragilis*. There are a number of new third-generation cephalosporins (cefoperazone, cefotaxime, ceftazidime, ceftriaxone). These drugs have been developed because of their relatively greater activity against Gram-negative bacteria. Although most retain some activity against Gram-positive bacteria, they are much less active than first-generation cephalosporins for staphylococci or other Gram-positive bacteria. Ceftriaxone has a longer half-life, allowing for once- or twice-daily dosage. It is also more active than cefoperazone against most Gram-negative bacteria.

Other cephalosporins

There are so many new cephalosporins that it is difficult to choose among them. It is recommended that the physician become familiar with the use of one oral and one parenteral drug in each generation. Dosage in children varies with each cephalosporin.

Aminoglycosides

The aminoglycosides are well tolerated by children and are of special utility in the treatment of complicated gram-negative UTI. They interfere with protein synthesis by binding proteins of the bacterial ribosomes.

Gentamicin

Gentamicin is probably the most widely used of the aminoglycosides in children and is especially effective against *Pseudomonas*. The usual pediatric dose is 5–7.5 mg/kg/day parenterally in two divided doses, depending upon age.[441] It achieves high tissue concentration and can be ototoxic, particularly to the vestibular cells. Nephrotoxicity also occurs in a small percentage of patients and should be watched for by checking serum creatinine periodically during the course of therapy. Nephrotoxicity occurs particularly frequently when gentamicin is given in combination with cephalosporins. Both ototoxicity and nephrotoxicity are usually transient.

Tobramycin

Tobramycin has the advantage of particular efficacy against *Pseudomonas*. It is said to be less nephrotoxic than gentamicin.[448] The dosage is 4–7.5 mg/kg/day given every 8–12 hours, depending upon age.[441]

Amikacin

A newer aminoglycoside, amikacin, was developed to improve activity against emerging resistant strains of *Pseudomonas*. As with other aminoglycosides, it is potentially both nephrotoxic and ototoxic. The dosage is 15–22.5 mg/kg/day given every 8–12 hours, depending upon age.[441]

Nalidixic acid

Nalidixic acid is an antibacterial agent that produces good urinary levels and is effective against Gram-negative organisms. It is especially effective against *Proteus*. Previous negative reports regarding the effectiveness of this agent can probably be accounted for by inadequate dosage.[449] Nalidixic acid is readily absorbed from the gastrointestinal tract and is well tolerated by children. It is rapidly inactivated by the liver. It is thought to interfere with DNA synthesis. The development of pseudotumor cerebri has been reported as a complication of its use in children. Nalidixic acid is available in both tablet and suspension form. The recommended dose is 55 mg/kg/day in four divided doses.[441]

Methenamine mandelate and methenamine hippurate

These agents are readily absorbed from the intestinal tract and remain inactive until they are excreted by the

kidney and concentrated in the urine. Methenamine is converted to the bactericidal agent formaldehyde in acidic urine; however, this conversion takes a minimum of 2 hours to achieve adequate bactericidal levels. Mandelic and hippuric acids are urinary acidifiers that have some additional inherent but weak antibacterial agent. Efficacy of methenamine may be enhanced further by supplementary urinary acidification, such as with ascorbic acid. Both can cause dysuria when administered in high doses, and methenamine mandelate has, on rare occasions, produced hemorrhagic cystitis.[450] The recommended dose for these agents initially is 100 mg/kg/day given orally in four divided doses, followed by 50 mg/kg/day in four divided doses.[441]

Tetracyclines

Tetracyclines should not be used in children under 8 years of age because they stain the permanent teeth. The need for tetracycline is extremely unusual in modern-day pediatrics.

Fungal, parasitic, and other inflammatory diseases of the genitourinary tract

8

William A Kennedy II

Fungal infections of the urinary tract

Candidiasis

Pediatric fungal inflammations of the genitourinary tract are becoming more common with both the increasing number of preterm infants surviving aggressive intensive care unit (ICU) management and the increasing number of immunocompromised children living with either malignancies, human immunodeficiency virus (HIV), or solid organ and bone marrow transplantation. Preterm neonates are often intubated for weeks, receive long-term hyperalimentation, and receive broad-spectrum antibiotics. Baley et al[1] report that systemic candidiasis will develop in as many as 4% of those weighing 1500 g and 10% of those weighing 1000 g. Prolonged survival of profoundly immunocompromised pediatric patients has likewise led to the emergence of fungal infections as the major cause of mortality and morbidity in advanced disease states. *Candida* is the leading bloodstream isolate from children hospitalized with opportunistic infections.[2]

Candida albicans is a yeast that belongs to the commensal flora of the mouth, intestinal tract, vagina, and skin. *Candida* is the most common of the opportunistic mycoses. Systemic disease occurs almost exclusively in patients with impaired host resistance. Conditions that predispose to candidemia include contamination of intravenous catheters, long-term antibiotic therapy, steroid administration, immunosuppressive agents, cytotoxic drug therapy, burns, and open surgical wounds.[3] Mokaddas et al[4] have also identified ICU stay, prior broad-spectrum antibiotic therapy, and surgery on the gastrointestinal tract as being additional risk factors for candidemia in the pediatric surgery patient.

The diagnosis of candiduria is made by urine culture. In the neonate, urine is obtained by suprapubic bladder tap or by percutaneous renal aspirate if renal candidiasis is suspected. Colony counts of greater than 10 000 *Candida* per 1 ml of urine signify infection.[5] Colony counts of 15 000/ml in midstream voided urine in males or straight catheterized specimens in females are evidence of renal *Candida* infection.[6] Urine specimens taken from indwelling catheters may have colony counts as high as 100 000/ml with no relationship to upper tract candidal infection.

Pediatric patients with renal candidiasis present with symptoms of urosepsis. Ureteral obstruction due to fungus ball infestation has been reported.[7] Anuria in infants can result from bilateral pelvic fungus balls.[8] Radiologic evaluation of these patients with ultrasound may demonstrate unilateral or bilateral hydronephrosis with an intrapelvic mass. Renal scan generally demonstrates that the involved kidney exhibits poor function. In patients with localized candidal cystitis, symptoms often consist of urinary urgency, frequency, and dysuria, or may be asymptomatic.

The treatment of candiduria is dependent on the extent of the infection. Candiduria that occurs in otherwise healthy children after long-term broad-spectrum antibiotic therapy should clear after the use of the antibiotic has stopped and usually requires no treatment except for local care when secondary skin irritation occurs. lnfections limited to the bladder may be controlled and eradicated by urinary alkalinization and/or intermittent instillation or irrigation with a solution of amphotericin B (5% in sterile water, shielded from light) via a three-way bladder catheter or intermittent catheterization.[9] Candidiuria confined to the upper collecting system may require treatment with oral 5-flucytosine (5-FC) or nephrostomy irrigation with amphotericin solution; however, 5-FC

should not be used in children with azotemia or bone marrow depression. Infants with obstructing renal fungus balls may at times require surgical removal via pyelotomy or percutaneous aspiration, followed by nephrostomy tube irrigation. Alkalay et al[10] also report the therapeutic use of forced diuresis with furosemide to clear fungus balls from the renal pelvis. Fluid intake and furosemide therapy were adjusted to keep a urine output at a level of 4 ml/kg/h to wash out the fungal bezoar.

The treatment of choice for systemic candidiasis is intravenous amphotericin B with or without the addition of 5-FC. Amphotericin B is nephrotoxic and must be carefully titrated to obtain appropriate serum levels. Peak serum levels should be twice the mean inhibitory concentration for the infectious organism and trough levels should be equal to the mean inhibitory concentration. The duration of therapy is dependent upon the extent of the disease; however, administration is often required for several weeks to eradicate systemic infections. Toxic side effects include fever, nausea and vomiting, generalized malaise, and renal failure. Monitoring of serum creatinine on an every other day schedule is necessary.

Other antifungal medications exist for the treatment of candidiasis. These include fluconazole, which has less associated nephrotoxicity and is therefore preferred by some physicians. Its use has steadily increased in such closed populations as the neonatal nursery. The gold standard of treatment still remains amphotericin B in the management of neonatal candidiasis, as the incidence of fluconazole resistance will probably increase given its recent widespread use in the neonatal nursery.[11,12]

Aspergillosis

Aspergillosis refers to a group of diseases caused by mycelial fungus of the genus *Aspergillus*. Aspergillosis is the second most common fungal infection in immunocompromised children.[13] Aspergilli are distributed worldwide, and spores are readily isolated from soil and decaying plants. Outbreaks of invasive disease usually occur among groups of immunocompromised children as a result of exposure to aerosolized spores at large construction sites near hospitals. Once the infection is acquired from inhalation of airborne spores, it is widely disseminated through hematogenous spread. The organisms may also be introduced through operative wounds, or indwelling foreign bodies such as intravenous or urinary catheters.

Microscopic hematuria and pyuria are often present in patients with aspergillosis. The fungi may be identified as branched septate hyphae on potassium hydroxide preparations of infected urine. Results of urine cultures are often inconclusive and multiple cultures may be required to make a diagnosis. Obstructive uropathy resulting from an aspergilloma in the renal pelvis may be the initial mode of presentation.[14] Invasive aspergillosis of the renal parenchyma is characterized by focal microabscess formation and occasional papillary necrosis.

Treatment of invasive aspergillosis remains high-dose intravenous amphotericin B. In patients with fungus balls in the renal pelvis, upper tract irrigation through a nephrostomy tube is indicated. Percutaneous or open surgical removal of obstructing aspergillomas is sometimes indicated.

Coccidioidomycosis

Coccidioidomycosis is an infection caused by a dimorphic fungus, *Coccidioides immitis*, that is found in the soil of the Western Hemisphere. Endemic areas in the United States are confined to the southwestern states, including Texas, New Mexico, Arizona, and California.

Genitourinary involvement occurs with disseminated disease. Autopsy studies[15] of patients with disseminated coccidioidomycosis indicate that renal involvement occurs in approximately 60% of the cases. Fungal involvement of the kidney is confined to the cortex as small miliary granulomas or microabscesses. Large, obstructive lesions within the renal pelvis do not occur as with other fungal infections. The radiographic findings of advanced renal coccidioidomycosis are similar to those of renal tuberculosis. They include infundibular stenosis, blunted or sloughed calices, and calcified granulomas.

Antifungal chemotheraphy is indicated for those at high risk for severe coccidioidomycosis and those with recognized disseminated disease. Currently available antifungal agents for use in treatment of coccidioidomycosis include amphotericin B, fluconazole, and ketoconazole. In the pediatric patient with rapidly progressing coccidioidomycosis, it is generally agreed that amphotericin B should be administered.

Parasitic infections of the urinary tract

Schistosomiasis

Schistosomiasis is a parasitic disease that infects more than 200 million individuals, primarily children and

young adults. Urinary schistosomiasis, or bilharziasis, is a vascular parasitic infection caused by the blood fluke *Schistosoma haematobium*. The disease is endemic in Egypt and has spread to areas of Africa, Asia, South America, and the Caribbean. Prevalence is increasing in many areas, as population density increases and new irrigation projects provide broader habitats for vector snails. Rare cases are seen in the United States and always originate from an endemic area.

Humans are infected through contact with water contaminated with crecariae, the free-living infective stage of the parasite. These organisms emerge from infected snails and penetrate the intact human skin. The crecariae change into schistosomula in the subcutaneous tissues and then migrate to the portal circulation where they reach sexual maturity. Adult worms then migrate to the perivesical and periureteral venous plexus. Upon fertilization, female worms deposit eggs in the small venules which eventually reach the lumen of the urinary tract. Eggs are passed into freshwater, where they hatch, infect freshwater snails, and begin the cycle anew (Figure 8.1).

Humans become infected with *Schistosoma* after coming in contact with contaminated water. Children of any age are most at risk due to activities such as swimming, bathing, and drinking this water. Acute schistosomiasis occurs between 3 and 9 weeks after infection and coincides with deposition of eggs in the bladder wall. The classic findings are terminal hematuria and dysuria. Bleeding can be so severe as to result in anemia. During the inactive phase of the infection, fibrosis and contracture of the bladder and distal ureter occur. The disease process is insidious and gross hydroureteronephrosis with renal insufficiency may occur before clinical symptoms appear.

Vester et al[16] recently defined the prevalence of schistosomiasis infection in an endemic region of Mali by screening 824 villagers. Infection ranged from 77% in adolescents to 51% in adults older than 40 years of age. Intensity of infection was generally low, with 91% excreting less than 100 ova per 10 ml

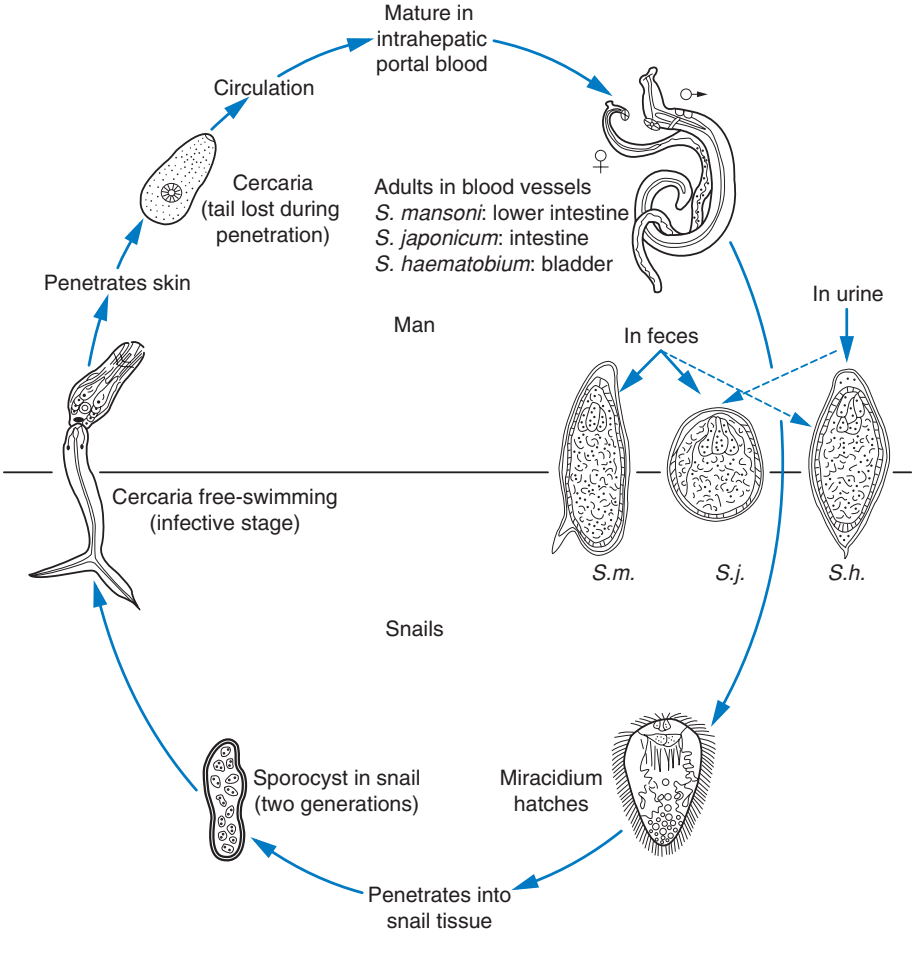

Figure 8.1 The life cycle of the schistosome. (Used with permission of the US Department of Health & Human Services, Public Health Services Publications, US Government Printing Office, Washington, DC, 1964.)

urine. Bladder wall enlargement and irregularities, bladder masses, and dilatation of the upper tracts were found ultrasonographically in approximately one-third of the individuals. Bladder lesions were more frequent in children than adults and correlated well with the intensity of the infection in younger age groups. The prevalence of urinary tract pathology dropped significantly with age, suggesting that either spontaneous resolution of urinary tract pathology occurs or the incidence in the population is increasing.

Schistosoma eggs produce a pronounced eosinophilic infiltrate within the bladder wall. As the disease progresses, collagen infiltration of the bladder occurs. There is deposition of calcareous material and ultimately sclerosis of the bladder due to calcification. Mucosal hyperplasia, squamous metaplasia, and epithelial dysplasia of the urothelium may occur at any stage of the disease process. Involvement of the trigone and bladder neck is most pronounced. Eventual bladder neck fibrosis may lead to outlet obstruction. Stasis of urine and urinary infections can predispose these patients to vesical calculi, whereas chronic bladder irritation predisposes these patients to squamous cell carcinoma. Vesicoureteral reflux is commonly reported in up to 50% of these patients as a result of fibrosis and lateral displacement of the intramural ureter.[17]

The diagnosis of schistosomiasis is established by the presence of terminal-spined eggs in the urine. A 24-hour urine collection with microscopic examination of the sediment is recommended. If infection is suspected and evaluation of the urine is negative, then cystoscopy and bladder biopsy may be performed. Peripheral blood examination will usually show eosinophilia. Anemia may be present with chronic infection due to destruction of erythrocytes by the blood fluke.

Calcification of the bladder wall presenting an eggshell appearance on plain film of the lower abdomen is classic for chronic urinary schistosomiasis. Hydronephrosis secondary to ureteral stricture may be found on imaging studies of the urinary tract. On cystoscopic evaluation of the bladder, bilharzial tubercles predominate over the trigone and posterior bladder wall.[17] Overdistention of the bladder results in bleeding. In patients with chronic disease, fibrosis and calcification of the tubercles in the submucosa form dull, granular 'sandy patches' that resemble grains of sand under water.

Various drugs are available for the treatment of urinary schistosomiasis. Most carry with them significant side effects. Management of children with schistosomiasis should be based on an appreciation of the intensity of the infection and the extent of the disease. The current drug of choice is praziquantel, which is effective against all species of *Schistosoma*. It is administered orally as a single or divided dose to a total of 40–60 mg/kg.[18]

Surgical intervention in schistosomiasis should be reserved until the effects of medical management can be assessed. Fibrosis and contracture of the bladder may require autoaugmentation, intestinal augmentation, or bladder replacement. Bilharzial strictures of the lower ureter can produce obstructive uropathy. Extensive fibrosis of the ureteral wall and the bladder mucosa usually precludes ureteroneocystostomy by traditional submucosal tunneling. Bazeed et al[19] suggest a method of partial flap ureteroneocystostomy to alleviate the obstruction. They report it to be effective in improving or stabilizing the upper tracts in 83% of individuals. Vesicoureteral reflux may develop in as many as 30% of these individuals after surgery.

Echinococcosis

Echinococcosis is the most prevalent human cestode infection in the world. It is commonly called hydatid cyst disease. There is virtually no part of the human anatomy that is immune from hydatid cyst disease. It is caused by the dog tapeworm *Echinococcus granulosus*. Although uncommon in the USA, it is endemic in the sheep-raising areas of the world such as Argentina, Australia, Spain, and Greece.

Humans are an intermediate host for the larval eggs of the adult tapeworm. The adult tapeworm lives in the intestinal tracts of dogs and sheds larval eggs which are excreted in the dog feces. Humans, as well as sheep, cattle, and pigs, may accidentally ingest these larval eggs through orofecal contamination. Dogs initially acquire the disease by swallowing the parasite scolices, which have become encysted in the liver or lungs of sheep, thus completing the life cycle of this parasitic worm.

In humans, the larval eggs pass through the intestinal wall and are widely disseminated throughout the body. Dissemination may occur by direct, vascular, or lymphatic invasion.[20] The primary organ affected in humans is the liver. Genitourinary involvement has been documented in the kidney, ureter, bladder, prostate, and epididymis.[21] The most common location for hydatid cyst disease in humans is the kidney. It is estimated that approximately 3% of all echinococcal infection involves the kidney.[22]

The largest series of pediatric echinococcosis was reported by Auldist and Myers,[23] who document 114 cases of hydatid cyst disease. Children of all ages were infected; however, manifestations of the disease are infrequently evident in children under 5 years of age. This is probably a result of the slow growth pattern of the hydatid cyst. The growth rate of hydatid cysts is estimated at 1 cm/year.[24] The cyst is typically very large at the time of initial presentation. The most common site of genitourinary infestation in the pediatric population is also the kidney. Hydatid cysts of the kidney usually present as a painful flank mass. Microscopic hematuria is present in the majority of the cases. Acute flank pain may be caused by rupture of the hydatid cyst into the collecting system. The passage of scolices (daughter cysts) may be associated with gross hematuria and urinary obstruction.[25]

Sonography has proved to be the most valuable tool in the diagnosis of hydatid disease. Hydatid cysts are easily uncovered on ultrasonographic evaluation of the abdomen in children. The coexistence of hydatid disease in other organs assists in the diagnosis. Plain films or computed tomography (CT) of the abdomen and pelvis may also reveal calcification within the walls of these cysts. The diagnosis of echinococcosis is usually suspected when there is a history of contact with sheep dogs in an endemic area of the world.

As humans are infected with only an intermediate stage of *Echinococcus*, the actual parasite cannot be routinely recovered from any easily accessible body fluid. If the hydatid cyst has ruptured into the collecting system, the recovery of scolices from the urine is pathognomonic for genitourinary echinococcosis. Serologic studies can also be useful in confirming the diagnosis of echinococcosis. Apt and Knierim[26] report that eosinophilia is present in one-third of the children affected with echinococcosis. Indirect hemagglutination and enzyme-linked immunosorbent assay (ELISA) testing are the most sensitive immunologic methods to diagnose human hydatidosis; however, false-positive reactions with other parasitic infections are possible.[20] Immunoelectrophoresis to detect specific antibodies against antigens isolated from hydatid cyst fluid is currently the most specific method of diagnosis of echinococcosis.[27]

Albendazole is the preferred drug for medical management of cystic hydatidosis. This drug therapy (15 mg/kg/day divided in three doses for 28 days) may be repeated for as many as four courses with 15 day drug-free intervals. A positive response may be seen in 40–60% of pediatric patients treated.[24] Ultrasonographic indications of successful therapy include flattening of the cyst, increase in echogenicity, and detachment of membranes from the cyst capsule. The factors predictive of success with chemotherapy are age of the cyst (>2 years old), low internal complexity of the cyst, and small size.[28]

Although previously thought to be contraindicated because of risk of anaphylaxis, percutaneous drainage of cysts under ultrasound guidance during albendazole therapy has become increasingly more successful for complete resolution of cystic disease. Spillage of cyst fluid is uncommon during aspiration. Nevertheless, systemic anaphylactic reactions are always possible with spillage of cyst fluid.

Surgical therapy is also an option for solitary lesions or failed medical management. Considerable care must be taken at the time of surgical resection to assure that there is no rupture of the cyst or spillage of cyst fluid during removal, as viable protoscolices may contaminate the surgical field, each capable of forming a secondary cyst wherever it lodges. There is also a risk of developing anaphylaxis as a result of spillage of cyst fluid at the time of surgical resection.

Enterobiasis

Pinworm infestation (enterobiasis) is caused by the nematode *Enterobius vermicularis*. Humans are infected by ingesting the eggs, which are usually carried on fingernails, clothing, or bedding. The adult worm lives in the large intestines of humans. The gravid adult female worm migrates at night to the rectum and deposits her eggs in the perianal and perineal skin. Perianal irritation during oviposition by female worms induces scratching. Eggs carried underneath the fingernails promotes reinfection and dissemination of the disease to others. The peak age of infection is between 5 and 14 years of age.

Enterobiasis has been implicated as a factor in acute and chronic urinary tract infections (UTIs). In a study of female children, Kropp et al[29] demonstrated that 22% of girls with documented UTIs had pinworm infestations compared with only 5% of an age-matched control population. They also report that the recovery of pinworms from the perianal region is higher in girls with enteric organisms present on a swab of their introitus.

Definitive diagnosis is established by either finding the parasitic eggs or recovering worms. Eggs can be easily detected by pressing adhesive tape against the perianal region early in the morning. The tape is then applied to a glass slide and it is examined under low-

power magnification. Repeated examinations, usually totaling three, are necessary to make a negative diagnosis.

Drug therapy should be given to all infected individuals. Pyrantel pamoate (11 mg/kg or maximum dose of 1 g) with a repeat dose at 2 weeks is the drug treatment of choice. Mebendazole (100 mg dose) with a repeat dose at 2 weeks is an alternative treatment. Neither is recommended in children under 2 years of age. Kropp et al[29] report a greater than 50% success rate in eradicating multiple recurrent UTIs in girls with concomitant pinworm infestation when the infestation is definitively treated.

Other inflammatory diseases of the urinary tract

Chlamydial infection

Chlamydia are obligate intracellular bacteria that are distinguished by a unique developmental cycle. Although they possess their own DNA and RNA, contain ribosomes, and have a cell wall, they lack the ability to generate adenosine triphosphate (ATP) and are therefore considered an energy parasite. *Chlamydia* alternate between an infectious metabolically inactive extracellular form, the elementary body (EB), and a non-infectious, metabolically active form, the reticulate body (RB). It is the EB that binds to specific receptor proteins on the cell membrane and enters the cell by endocytosis. Within 12 hours of ingestion, the EB then differentiates into the RB form and undergoes binary fission. This results in the typical intracytoplasmic inclusion bodies characteristic of a chlamydial infection. After approximately 36 hours, the RB differentiates back into an EB and is then released from the cell by a process of exocytosis.

Chlamydia trachomatis is the only one of the four chlamydial species that commonly infects the human genitourinary tract and causes human oculogenital diseases. *Chlamydia trachomatis* is thought to be responsible for the majority of non-gonococcal urethritis and pelvic inflammatory diseases in adolescents. Rettig and Nelson[30] also documented the coexistence of *Chlamydia* in boys with anogenital gonorrhea.

Chlamydial infections in children should be divided into two categories: perinatally transmitted infections and sexually transmitted infections in older children. Cervical chlamydial infections are reported in approximately 25% of pregnant women. Active chlamydial infections at the time of pregnancy may be transmitted to the infant at the time of vaginal delivery. The risk of transmission from mother to child is about 50%.[31] Conjunctivitis and pneumonia are the most common perinatally transmitted chlamydial infections. Genitourinary sites of perinatal transmission include the vagina and urethra. Perinatally transmitted vaginal, urethral, or rectal infections may persist for 3 years with minimal or no symptoms; therefore, the presence of *Chlamydia* is not necessarily an indication of child abuse.

The most common chlamydial infections in older infants and children include vaginitis in girls and urethritis and epididymitis in boys. In boys, the most common symptom of chlamydial urethritis is a clear mucoid urethral discharge. It may be associated with or without urinary urgency and frequency. In girls, acute inflammatory changes in the vagina or cervix may lead to mucopurulent discharge.

The definitive diagnosis of chlamydial infection includes isolation by culture of the organism from the urethra in boys and endocervical region in girls. Several non-culture methods have also been approved by the US Food and Drug Administration (FDA) and include a direct fluorescent antibody test or an enzyme immunoassay. Newer tests for the diagnosis of chlamydial infections include a DNA probe and a polymerase chain reaction assay. These two assays have not yet been approved for testing in children.

Antibiotics are the mainstay of therapy for chlamydial infections in children. These antimicrobials, usually sulfonamides, erythromycin, and tetracyclines, are typically given for 10–14 days; tetracyclines should not be administered to children under the age of 8 years because of the resulting dental discoloration that may occur.

Viral cystitis

Viral cystitis causes irritative voiding symptoms and hematuria in infants and children. In the toilet-trained and older child, it is characterized by severe urinary frequency, urgency, incontinence, and gross hematuria with a negative urine culture for bacteria. Severe hemorrhagic viral cystitis is seen more frequently in pediatric patients undergoing bone marrow transplantation.[32] Viral cystitis also commonly occurs in the child infected with HIV. Viral infections can often be life threatening in these immunocompromised patients.

The usual causative viruses are adenovirus types 11 and 21, influenza A, and cytomegalovirus.[33] Studies

of acute hemorrhagic cystitis in Japanese and US children revealed adenovirus type 11 as the most common cause. It was noted that 51% of the Japanese children and 23% of the US children had adenoviruria during their episode of hemorrhagic cystitis. In both populations male outnumbered female patients by a ratio of nearly 2–3:1.[33] Viral shedding may continue throughout the duration of the illness and may last from 4 days to 2 weeks. Herpes zoster involving the bladder may also cause bladder irritative symptoms.

The diagnosis of adenoviral cystitis can be made by the immunofluorescence of adenoviral antigen in exfoliated bladder epithelial cells in the urine of these patients, although this is not commonly done.[34] Since viral cystitis is not an ascending infection, routine voiding cystourethrography (VCUG) as part of the evaluation is not necessary if the diagnosis is confirmed. Radiographic changes within the bladder are remarkable and often resemble that of a bladder sarcoma, and ultrasonography may show a diffusely thickened bladder wall (Figure 8.2). These changes usually resolve within 2–3 weeks. If complete resolution of sonographic bladder wall thickening occurs, then cystoscopy is unnecessary. These infections are self-limited and supportive care with hydration is often all that is necessary.

Polyoma BK virus is frequently identified in the urine of bone marrow transplant patients with hemorrhagic cystitis.[35] The diagnosis of BK viruria is made by identification of epithelial cells within the urine containing intranuclear inclusion bodies suggestive of BK virus and a positive polymerase chain reaction test for BK virus in the urine. Arthur et al[36] report that the viruria occurred exclusively in patients who were seropositive at transplantation, indicating a reactivation of the virus. Many immunocompromised patients do not respond to traditional therapies for hemorrhagic cystitis and may progress to acute renal failure (Figure 8.3), which may be fatal.[37]

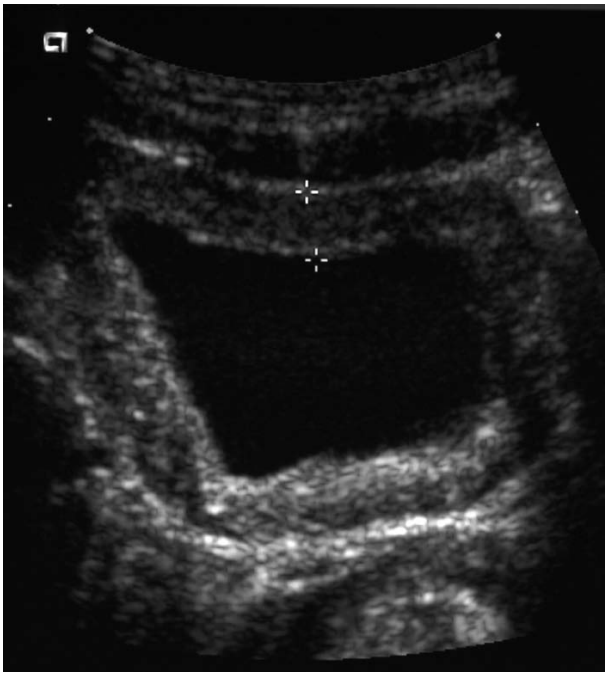

Figure 8.2 Diffusely thickened bladder wall of a 6-year-old boy with adenovirus cystitis.

The immunocompromised pediatric patient may require additional management. The use of ribavirin, an intravenous antiviral agent, has been suggested for treatment of acute adenovirus hemorrhagic cystitis.[38] If treatment with aggressive fluid hydration and forced diuresis with furosemide has failed to control symptoms of hemorrhagic cystitis, some clinicians have advocated the instillation of prostaglandin E_1 into the bladder for up to 7 days[39] before resorting to chemical fulguration with alum or formalin for those with intractable bleeding. Laszlo et al[40] have recommended direct instillations of prostaglandin E_2 into the bladder of patients infected with BK virus presenting with hemorrhagic cystitis. They report resolution of hematuria in all cases within 5 days of initial treatment. Novel therapies such as hyperbaric oxygen treatment have also been reported in cases that are refractory to all conventional treatments.[41]

Eosinophilic cystitis

Eosinophilic cystitis is a rare inflammatory disorder of the urinary bladder, also characterized by irritative voiding symptoms. Symptoms are non-specific, with the most common being dysuria, frequency, lower abdominal discomfort, and hematuria.[42] Children may present with a palpable suprapubic mass on physical examination. Occasionally, this may be mistaken for a pelvic sarcoma.[43] Often the child will have a history of allergies. Eosinophils in the urine or peripheral blood eosinophilia, although diagnostically helpful, are frequently not found.[44]

Imaging studies of the bladder usually begin with sonography. Focal thickening of the bladder wall may be evident as well as hydronephrosis and hydroureter if the lesion affects the region of the ureteral orifice. These findings are similar to those of bladder sarcoma.[45] The definitive diagnosis is established by cystoscopy and bladder biopsy. Cystoscopic findings include erythematous, velvety, raised plaques. The

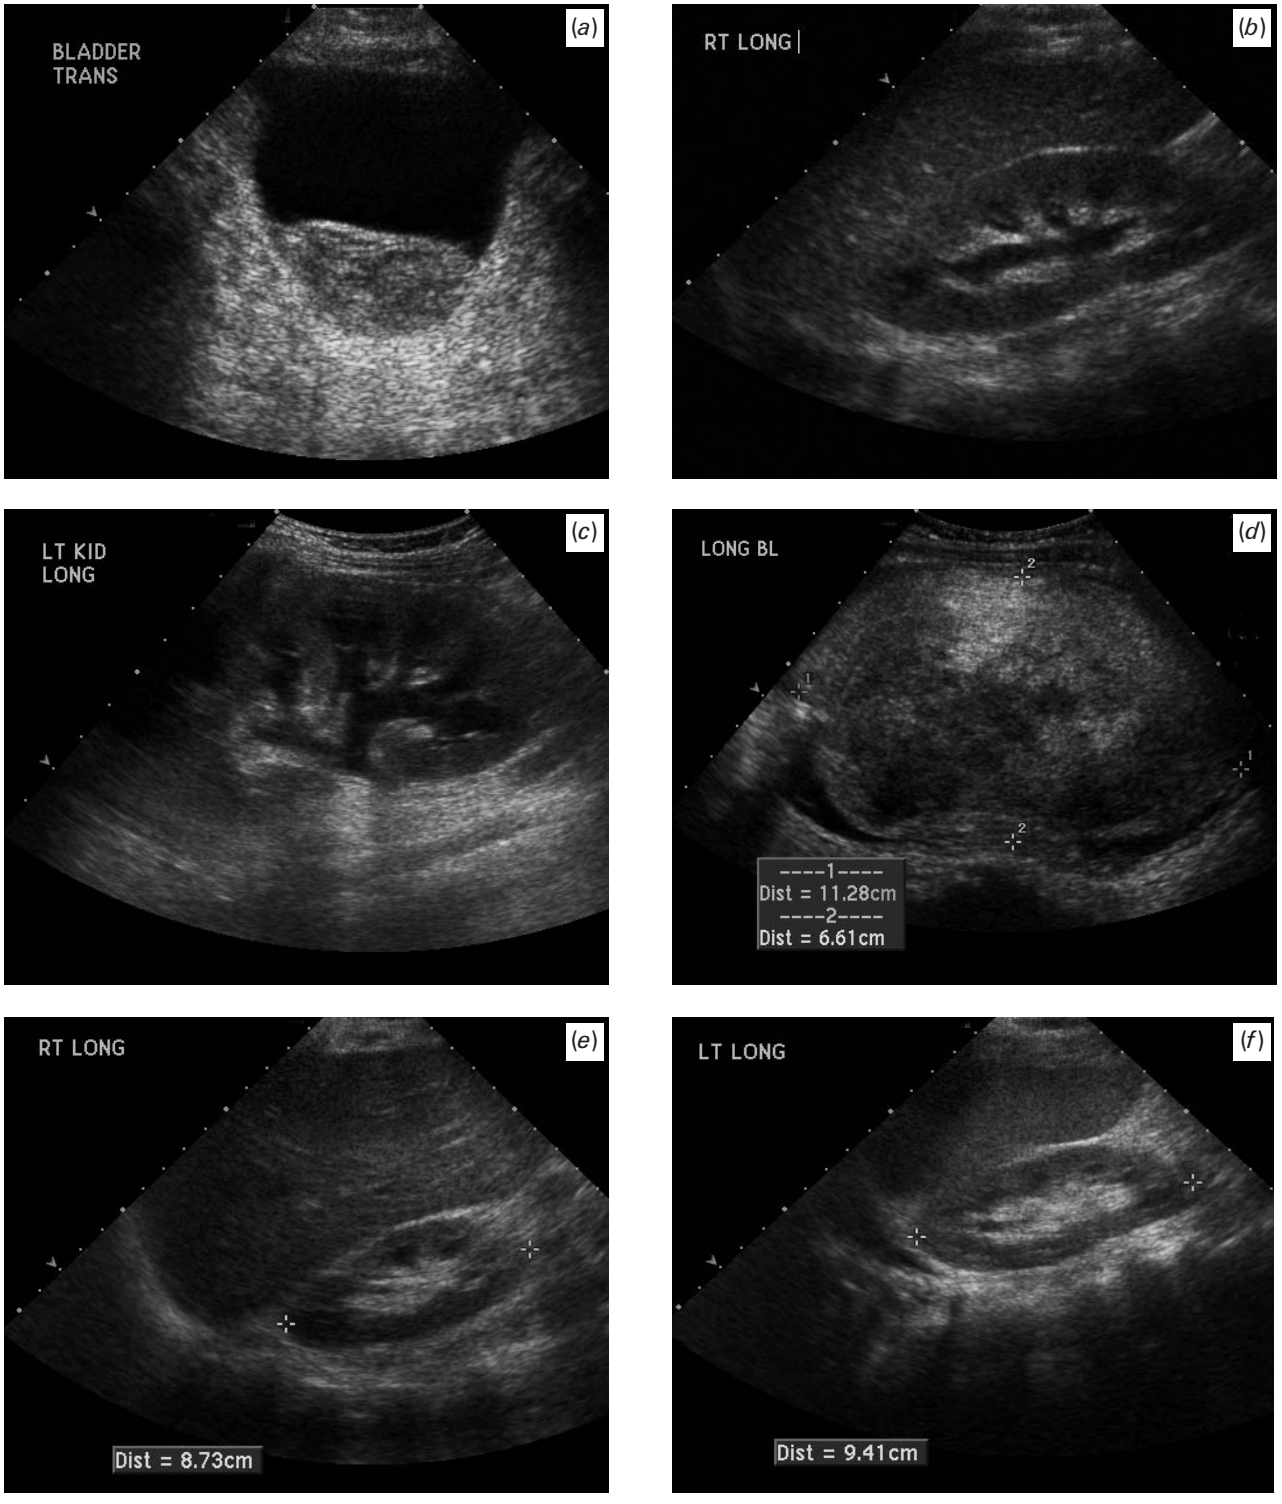

Figure 8.3 Urinary sonography of a 4-year-old boy s/p status post bone marrow transplant with hemorrhagic cystitis due to BK viruria. (*a–c*) Bladder, right kidney, and left kidney at time of initial presentation; (*d–f*) bladder, right kidney, and left kidney at time of death due to renal failure.

mucosa is often edematous with areas of ulceration.[46] Eosinophilic cystitis in children affects all parts of the bladder. Urethral involvement has been seen in only one case.[47]

Biopsy shows a classic eosinophilic infiltration in the lamina propria and muscle layers of the bladder. There may be muscle necrosis or significant muscle fibrosis. Giemsa stain for eosinophils and trichrome

stain for muscle fibrosis are helpful in making the diagnosis.[48] Electron microscopy is also a useful diagnostic aid. If eosinophils are degenerating, ultrastructural examination may be the only way of documenting their presence.

The true etiology of eosinophilic cystitis remains unknown. An immunoglobulin E (IgE)-mediated allergic cause has been suggested given the strong allergic histories of the patients. Food allergens, drugs, and other substances have been implicated.[49] It has been postulated that various inciting agents such as bacteria and foreign protein act as antigenic stimuli in the bladder to produce an eosinophilic infiltration. The antigens form immune complexes, resulting in the release of lysosomes that break down bladder tissue and result in inflammation.

The treatment of eosinophilic cystitis involves removing the antigenic stimulus if present and identifiable. Identification of the antigenic stimulus may be difficult in a pediatric population. In a cohort of 8 pediatric patients who presented with eosinophilic cystitis, an identifiable cause (i.e. parasitic infection) could be found in only one case. The role of antihistamines and steroids is unclear. Sutphin and Middleton[50] reported that of these 8 patients with biopsy-proven eosinophilic cystitis, only 2 received antihistamines and steroids. These individuals showed resolution of their symptoms and radiographic findings within 2 weeks. The other untreated pediatric patients also resolved their symptoms; however, the mean interval to resolution was greater than 7 weeks. The prognosis for children with eosinophilic cystitis is generally very good. Almost all reported cases in the literature resolved within 12 weeks.

Despite the apparent self-limited course of eosinophilic cystitis, it should be kept in mind that recurrence of this disease is possible. Documented recurrences have been reported several years after the initial event.[51] It has been hypothesized that local surgical trauma to the bladder or an anesthetic agent may be the cause for recurrence. A recommendation for pretreatment with steroids and antihistamines prior to bladder surgery has been made for patients with a previous history of eosinophilic cystitis.[51]

Malacoplakia

Malacoplakia is an unusual benign granulomatous condition that was first recognized by Michaelis and Gutmann in 1902.[52] It has been postulated that the cause is the defective digestion of phagocytosed bacteria due to an intracellular abnormality of macrophage function.[53] Microscopically, malacoplakia consists of large macrophages mixed with lymphocytes and plasma cells. Michaelis–Gutmann bodies are evident on histologic evaluation. They are rounded intracytoplasmic inclusions with a concentric 'owl-eye' appearance (Figure 8.4). The Michaelis–Gutmann bodies contain incompletely digested bacterial components mineralized with iron and calcium phosphate salts.

In an adult population, malacoplakia affects the bladder in about 40% of cases.[55] Conversely, in a pediatric population, a wide variety of organs such as the tongue, gastrointestinal tract, lungs, brain, adrenals, and retroperitoneum may be involved, but the most common genitourinary site appears to be the kidney as opposed to the bladder. Although Witherington et al[54] describe a case of bladder malacoplakia in a child with recurrent UTIs, vesicoureteral reflux, and a selective IgA deficiency, in general renal malacoplakia is reported more frequently and may involve one or both kidneys.

Pediatric genitourinary malacoplakia occurs in the setting of recurrent UTIs, usually with *Escherichia coli*.[55] Renal malacoplakia is suspected in the pediatric patient when response to traditional antimicrobial therapy does not occur. These patients often have persistent nephromegaly without abscesses demonstrated by either ultrasonography or CT. Diagnosis is usually confirmed by renal biopsy (either open or percutaneous), showing chronic parenchymal inflammation with Michaelis–Gutmann bodies. Recent reports[56]

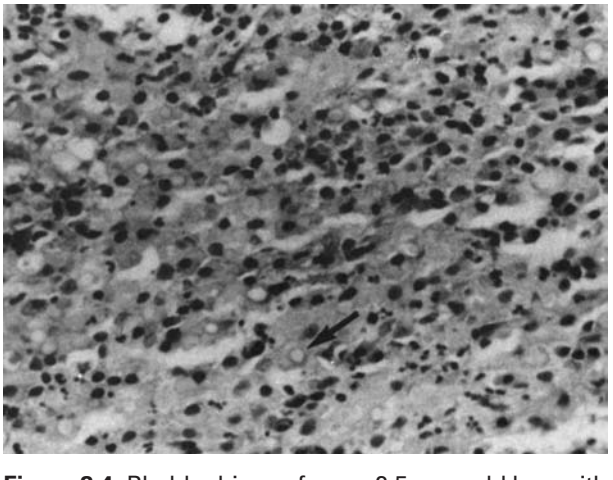

Figure 8.4 Bladder biopsy from a 2.5-year-old boy with *E. coli* urinary tract infection and hematuria. Inflammatory reaction with Michaelis–Gutmann body (arrow) seen in the lamina propria. (Reproduced with permission of Witherington et al.[54])

have confirmed the diagnosis by cytologic evaluation of a renal fine-needle aspirate.

Previously, bilateral renal malacoplakia in the pediatric population was considered a fatal disease. Unilateral disease was frequently treated with nephrectomy. Honjo et al[57] suggest a conservative treatment plan consisting of an immunomodulating regimen. Patients should receive antimicrobial therapy using an antimicrobial agent with intracellular activity (i.e. trimethoprim–sulfamethoxasole), with immunomodulating pulse therapy with methylprednisolone and intravenous G-CSF (granulocyte colony-stimulating factor). If a patient is on immunosuppressive therapy, they recommend appropriate reductions. With the advent of such treatment, nephrectomy may no longer be mandatory in renal malacoplakia and the disease is no longer fatal in the pediatric population.

Other inflammatory diseases of the genitourinary tract

Epididymitis

Epididymitis has been traditionally thought of as a rare occurrence in a pediatric population. It results from an inflammatory reaction of the epididymis to an infectious agent, a chemical irritant, or a non-specific cause. Although infection with bacteria or viral organisms is thought to be the cause of epididymitis, the majority of documented cases are not associated with culture-proven UTIs.[58] Sterile urine in the epididymis may also be sufficient to incite an inflammatory reaction. Epididymal infection may therefore occur as a result of retrograde passage of urine through the ejaculatory ducts,[59] hematogenous spread from a systemic infection, or direct extension from a pre-existing orchitis.

Boys with epididymitis usually present with scrotal pain and edema. They are exquisitely tender to palpation in the region of the epididymis and the vas deferens. A reactive hydrocele may also be present. The differential diagnosis of epididymitis in a child must always include testicular torsion, torsion of an appendix testis, and idiopathic scrotal edema. The onset of pain in boys with epididymitis is often more insidious than in boys with torsion of the testis or appendix testis. Careful physical examination and radiologic imaging studies with either Doppler ultrasound or radionuclide testicular scanning will often aid in making the correct diagnosis. If a definitive diagnosis of epididymitis cannot be arrived at, then surgical exploration may be required to exclude testicular torsion.

The use of a urinalysis in making the diagnosis of epididymitis would seem to be a valuable discriminator; however, it is often inconclusive. Gislason et al[60] showed that only 24% of patients with epididymitis had greater than 10 white blood cells per high power field on urinalysis at the time of presentation. Urinalyses have also been abnormal in 10% of boys that present with testicular torsion.[61] Urine cultures are also unrewarding in making the diagnosis of epididymitis, as only 12.5% were positive in the cohort of boys with epididymitis that were retrospectively studied by Gislason et al.[60]

The evaluation of a boy with epididymitis should not end once the diagnosis has been confirmed. This relatively rare problem in boys is often enigmatic in its etiology. In prepubertal boys, infection in the epididymis may result from an anatomic defect such as a urethral obstruction (urethral valves or meatal stenosis) or an ectopic ureter draining into the seminal vesicle or vas deferens.[62] Urologic investigational procedures after resolution of the inflammation should be performed. Urologists vary widely in their recommendations for radiologic examinations. Most agree that at a minimum an upper tract evaluation with an ultrasound should be performed for culture-proven bacterial epididymitis. Excretory urography would be the imaging study of choice for an ectopic ureter draining to the seminal vesicles, while VCUG would demonstrate urethral anomalies and reflux of urine into the ejaculatory ducts. If the epididymitis was associated with a documented bacterial UTI, VCUG should be performed.

Dysfunctional voiding in older boys has been proposed as an etiology for epididymitis.[63] External sphincter spasm is thought to facilitate retrograde urine flow through the vas deferens. A report of 56 boys with epididymitis revealed that nearly 25% had dysfunctional voiding tendencies associated with epididymitis. Therefore, the addition of a detailed voiding history and use of non-invasive urodynamic testing with uroflow, patch electromyography, and ultrasonographic residual urine assessment has been advocated for boys over the age of 5 years that present with epididymitis. Congenital urologic anomalies are a less frequent cause of epididymitis in the absence of documented bacterial infection.

The treatment of acute epididymitis includes scrotal support and elevation, and analgesic and anti-inflammatory medications. If a bacterial infection is

likely, an antibiotic may be started after obtaining a urine culture. Once the acute infection is treated, age-appropriate studies to determine the etiology of the epididymitis should be undertaken.

Vulvovaginitis

Vulvovaginal inflammation is the most common gynecologic complaint of the prepubertal girl. Most cases are initially treated by the primary care physician, with referral to the pediatric urologic specialist only when symptoms persist.

The majority of girls have a profuse, thick vaginal discharge during the newborn period that is primarily a response to the perinatal stimulation of circulating maternal hormones. This should not be mistaken for a pathologic process. At puberty, both the vulvar and vaginal tissues are once again stimulated by circulating estrogens and therefore swelling and discharge may be expected.

Vulvovaginitis is most commonly seen in prepubertal females between the ages of 2 and 7 years. The child is typically brought to the physician with complaints of discharge, discomfort, pruritus, and often urinary symptoms such as burning with voiding. The parents frequently note a discharge present in the child's diaper or undergarments. An abnormal odor and/or redness of the vulva may also be described.

There are several reasons to explain why young girls are particularly susceptible to vulvovaginitis. Anatomically, the vulva of the young girl is relatively unprotected, lacking the labial fat pads and pubic hair of the postpubertal girl. Vulvar skin is also thin, sensitive, and easily irritated by minor trauma. In addition, the vaginal mucosa is also thin in this age group. The vaginal cavity in these prepubertal girls is also an excellent culture medium for bacteria with its neutral pH and warm, moist environment. These obvious structural and biologic differences make the vulvovaginal environment of prepubertal girls particularly sensitive to inflammation. In addition, children tend to have poor hygiene habits when compared with adolescents. They do not practice good handwashing and often play in areas that expose them to dirt and sand, creating chronic irritation of the vulva. The presence of a foreign body or suspected sexual abuse must also be considered in the list of risk factors for vulvovaginitis in the prepubertal girl.[64]

In evaluating the young child with vulvovaginitis, the preceding risk factors should be kept in mind. A complete history and detailed perineal examination must be performed. The history should include information concerning the onset of the condition and any therapies previously instituted for treatment. A history of potential chemical irritants should be elicited (i.e. bubble baths, soaps, powders). A previous surgical history and family history of diabetes, eczema, or contact sensitivities should be addressed. The child's social setting should also be reviewed for information regarding potential child abuse (i.e. primary care giver, day care, contact with older children). The physical examination should look for evidence chronic illness, dermatologic problems, or traumatic injury. Most girls can be comfortably examined in the frog-leg position without the aid of sedation. Some sexual abuse experts recommend a knee–chest position for a complete examination. Cultures may be obtained by a sterile saline-moistened swab or a saline flush of the vaginal introitus. If bleeding or malodorous discharge raises the issue of a foreign body, then formal vaginoscopy may need to be undertaken under anesthesia. If a persistent and continuous flow from the vaginal introitus is present, then an ectopic ureter may enter the differential diagnosis. In this situation, ultrasonography or excretory urography will assist in confirming the diagnosis.

The treatment of vulvovaginitis depends entirely on the etiology of the inflammation. Non-specific vaginitis accounts for the majority of these prepubertal cases. It is thought to involve alterations in the normal flora of the vagina, resulting in vulvar and distal vaginal inflammation. The vagina of a prepubertal girl is typically colonized with the same variety of bacteria as observed in older women. It may be appropriate to request colony counts on all organisms recovered from culture, as overgrowth by one particular organism may warrant antimicrobial therapy directed at that organism. Routine treatment of non-specific vaginitis is usually directed toward improved hygiene, avoidance of irritating stimuli, and techniques to promote drying of the vulva, such as wearing loose-fitting clothing at night.

Specific vaginitis in prepubertal girls may be the result of infections with *Candida albicans* and *Enterobius vermicularis*. Treatments of these infections have been previously outlined. Other causes of specific vaginitis include sexually transmitted organisms, resulting in gonorrhea, chlamydia, and herpes. The treatment of these infections is outlined in Table 8.1. These organisms may be acquired during passage of the newborn through the birth canal or may result from sexual abuse. The age at presentation, along with social history and physical examination, will suggest the etiology.

Table 8.1 Treatment of specific vulvovaginitis

Specific infection	Treatment
Gonorrhea	Ceftriaxone sodium 50–75 mg/kg IM *not to exceed* adult dose of 250 mg IM (one-time IM dose only) If allergic: tetracycline[a] 40 mg/kg for 7 days
Chlamydia	Tetracycline[a] 40 mg/kg PO for 7 days
Gardnerella vaginalis	Metronidazole 15 mg/kg PO
Herpes	Acyclovir 1200 mg/day PO for 7–10 days

[a] Not to be used in children under 8 years old.

Malodorous discharge with associated vaginal bleeding should alert the clinician to the possibility of the presence of a foreign body within the vagina. Eighty percent of all foreign bodies present within the vagina are wads of toilet tissue lodged in the vaginal vault.[65] This may result in both an infectious and inflammatory response. Various other foreign bodies have been recovered, including coins, safety pins, pen tops, fruit pips, and small toys.[66] The probability of foreign bodies being recovered from the vagina of prepubertal girls presenting with vulvovaginitis is 4%.[67] The inflammatory response associated with the presence of the foreign body resolves with the removal of the object.

Idiopathic scrotal and penile edema

It is well known that acute scrotal swelling in children may be primarily due to conditions such as testicular torsion, torsion of the appendix testis, epididymo-orchitis, acute hydrocele, or incarcerated inguinal hernia. There is, however, a lesser-known clinical entity called idiopathic scrotal edema which is characterized by painful scrotal swelling. This is a distinct diagnosis that may be responsible for up to 20% of cases of acute scrotal inflammation.[58] It will typically present in boys between the ages of 1 and 14 years.[68]

The largest single series of idiopathic scrotal edema was reported by Evans and Snyder,[69] in which they retrospectively reviewed 30 cases in 26 patients over an 8-year study period. These boys usually exhibited a sudden 1 day onset of unilateral or bilateral scrotal erythema, which was minimally tender. The edema may frequently extend onto the anterior abdominal wall or the perineum. The child is frequently afebrile, with a normal urinalysis and normal peripheral white blood cell count. Occasionally, eosinophilia is present. When examined early in the process of scrotal swelling, the spermatic cord and testes should feel normal. Characteristically, the clinical findings resolve in 1–2 days. Kaplan[68] reported that in his series of 6 patients, the examiner had the distinct impression that the edema was confined to the superficial layers of the scrotum and that it rarely extended to the penis. Lau and Ong[70] reported that a similar benign and self-limiting condition of the penis exists which is suspected to be a variant of idiopathic scrotal edema.

If the diagnosis is uncertain, then imaging studies may be necessary. Radionuclide testicular scanning or Doppler ultrasonography may be necessary to exclude testicular pathology. On physical examination, this can often be assessed by manipulation of the testis into the superficial inguinal pouch where it can be noted to be palpably normal and non-tender. In rare instances when diagnostic uncertainty still exists, surgical exploration to rule out testicular pathology will reveal a normal testis and epididymis with inflammation confined to the scrotal wall.

There has been much speculation on the etiology of acute idiopathic scrotal edema. Infection with cellulitis was thought to be the etiology until multiple studies revealed negative intraoperative cultures, no elevation of peripheral white blood cell count, and normal urinalysis and culture.[69] The process is also self-limiting and resolves without the use of antibiotics. Insect bites were also entertained as an etiology; however, the lack of a lesion characteristic of a bite has made this less likely. Allergy has also been suggested as an etiology, especially given the presence of eosinophilia in selected cases. In no case, however, has a particular allergen been identified, and the majority of these patients are not characterized as having an allergic diathesis.[68]

Evans and Snyder[69] suggest that idiopathic scrotal edema bears a strong resemblance to angioedema, which is characterized by a localized painless swelling of the subcutaneous tissue of various body parts. The overlying skin is usually normal in color and temper-

ature, but slightly reddened. The chief sensation is one of distention. The individual lesion may persist from 1 to 3 days. Angioedema results from a dilation of small blood vessels, with a transudation of fluid through the capillaries. These vascular changes are believed to be mediated by a local derangement of histamine release. Recommended therapy should consist of reassurance and perhaps a short course of antihistamines.

Interstitial cystitis

Interstitial cystitis is a chronic, debilitating bladder disease of unknown etiology that is seldom reported to occur in children. The first report of the disease was made by Skene in 1878.[71] Since that initial report, there are only a handful of manuscripts that document this disease process in the pediatric population.[72–74]

Patients with interstitial cystitis typically have severe sensory urgency with urinary frequency and bladder pain that may be alleviated with voiding. Cystoscopy after hydrodistention in these patients will show changes varying from petechial hemorrhage in regions with no ulcers to other regions with classic Hunners's ulcers.[75] Middle-aged women constitute the majority of patients with interstitial cystitis. It is less frequently reported in men and rarely documented in children.

Chenoweth and Clawater[72] were the first to report interstitial cystitis in children. In their series of seven cases, they describe the presenting signs and symptoms as:

- day and night frequency of urination
- abdominal pain
- decreased bladder capacity
- negative urinalysis and culture.

In addition, these children were described as being extremely nervous and tense, resting poorly, crying frequently, and having poor appetites. Farkas et al[73] report that the pediatric cases of interstitial cystitis are more common in adolescent girls.

Close et al[74] reported the first large retrospective analysis of interstitial cystitis in the pediatric population, distinguishing this group of patients from the hundreds of individuals that present with voiding dysfunction. They characterized a group of 16 individuals who presented over a 12-year period. Unlike previous pediatric and adult reports, there is less of a female preponderance, with 70% girls and 30% boys in the study population. The most common presenting symptom was urinary frequency and urgency (88%), followed by abdominal pain relieved by voiding (81%). All patients had negative urinalysis and urine culture.

Diagnostic evaluation of pediatric patients suspected of having interstitial cystitis consists of cystoscopy with hydrodistention. Close et al[74] report that all patients had diffuse glomerulations and terminal hematuria after hydrodistention (60–70 cmH_2O for 1–2 minutes). Bladder biopsies, obtained in select cases, revealed chronic inflammation with lymphocytic infiltrate. No mast cells or eosinophils were noted. Urodynamic evaluation demonstrated early bladder filling sensation with no evidence of involuntary bladder contractions. Bladder capacity is also significantly reduced in these individuals. Poor bladder compliance was only documented in approximately 40% of patients.[74]

Treatment of interstitial cystitis in children is met with the same disappointing results as in adults. Bladder distention may temporarily alleviate symptoms.[72–74] Repeated hydrodistentions were required by 50% of the patients reported by Close et al.[74] In rare circumstances chlorpactin instillations have been utilized with temporary and incomplete relief of symptoms.[72] Although bladder augmentation with intestine has been reported as a treatment option,[73] inflammatory changes consistent with interstitial cystitis have been found in the bowel segment on follow-up. Surgical management of this disease in children should be considered only when all other treatment options have failed and the diagnosis has been absolutely confirmed.

Pain management for the pediatric urologic patient

9

Stephen C Brown and Patricia A McGrath

Introduction

When we were asked to contribute a chapter in a major textbook in urology, I was keen on the idea for several reasons. If you look at many surgical textbooks from 10 years ago, pain was often not even mentioned. In the last few years, pain has made it to the radar screen, but only in a cursory fashion. In this chapter we wish to expand on the surgeon's ability to assess, treat, and more fully understand the complex entity of pain, with the result being to further decrease pain in children. Should a psychological theme in treating pain be explored in a surgical textbook of urology? I feel it is not only important but also essential.

Pain control is an integral component for the pediatric patient undergoing procedures and ongoing care by the urologist. Children may experience many different types of pain from invasive procedures or operations, the cumulative effects of toxic therapies, progressive disease, or psychological factors. While acute postoperative pain is often straightforward to treat, some cases can be complex, with pain resulting from multiple nociceptive and neuropathic components. In addition, several situational factors usually contribute to children's pain, distress, and disability. Thus, to adequately treat pain in children receiving care by the urologist, we must evaluate the primary pain sources. Some cases may require us to ascertain which situational factors are relevant for which children and families, where treatment emphasis would shift accordingly from an exclusive disease-centered framework to a more child-centered focus.

In this chapter, we describe a child-centered framework for understanding and controlling pain for children undergoing procedures and ongoing care by the urologist. Pain control should include regular pain assessments, appropriate analgesics administered at regular dosing intervals, adjunctive drug therapy for symptom and side-effects control, and non-drug interventions to modify the situational factors that can exacerbate pain and suffering. This chapter describes the unique nature of children's pain, including the primary factors that affect their pain and quality of life, presenting guidelines for selecting and administering drug therapy in accordance with the nociceptive and neuropathic components, and recommending practical non-drug therapies for integration within a hospital or home setting.

Guidelines for assessment, analgesic selection and administration, and non-pharmacologic interventions

The principles of analgesic therapy, the guidelines for drug administration, and the guidelines for a supportive cognitive-behavioral approach are those that should be followed in all pediatric care.

Pain assessment

Pain assessment is an integral component of diagnosis and treatment for children. A thorough medical history, physical examination, and assessment of pain characteristics and contributing factors are necessary to establish a correct clinical diagnosis. Subsequent assessments of pain intensity enable us to determine when treatments are effective and to identify those children for whom they are most effective. Healthcare providers need pain measures that are convenient to administer and whose resulting pain scores provide meaningful information about children's pain experiences. An extensive array of pain measures have been developed and validated for use with infants, children, and adolescents.[1–3]

Like adult pain measures, children's pain measures

are classified as physiologic, behavioral, and psychological, depending on what is monitored – physical parameters (e.g. heart rate, sweat index, blood pressure, cortisol level), distress behaviors (e.g. grimaces, cries, protective guarding gestures), or children's own descriptions of what they are experiencing (e.g. words, drawings, numerical ratings). Physiologic and behavioral measures provide indirect estimates of pain because healthcare providers must infer the location and strength of a child's pain solely from his or her responses. In contrast, psychological measures can provide direct information about the location, strength, quality, affect, and duration of the pain.

The criteria for an accurate pain measure are similar to those required for any measuring instrument. A pain measure must be valid, in that it measures a specific aspect of pain, so that changes in pain ratings reflect meaningful differences in a child's pain experience. The measure must be reliable, in that it provides consistent and trustworthy pain ratings, regardless of the time of testing, the clinical setting, or who is administering the measure. The measure must be relatively free from bias, in that children should be able to use it similarly, regardless of differences in how they may wish to please adults. The pain measure should be practical and versatile for assessing different types of pain (e.g. disease-related, procedural pain) in many different children (according to age, cognitive level, cultural background) and for use in diverse clinical and home settings.

Physiologic and behavioral pain scales

Although physiologic parameters can provide valuable information about a child's distress state, more research is required to develop a sensitive system for interpreting how these parameters reflect pain strength. At present, there are no valid physiologic pain scales for children.

Most behavioral pain scales are checklists of the different distress behaviors that children exhibit when they experience a certain type of pain.[1,4,5] To develop these scales, trained healthcare providers carefully observe children when they are in pain (e.g. after surgery) and document any behaviors that seem caused by the pain. They then list these 'presumed pain' behaviors (e.g. crying, facial expression, limb rigidity) on an itemized checklist. Parents complete the pain scale by checking which of the listed behaviors they see when children are ill. On many scales, parents also rate the intensity of the behaviors. The intensity scores for each of the observed behaviors are summed to produce a composite pain score. Although most behavioral scales measure acute pain, recent attention is focused on the need to develop sensitive measures for children who are cognitively or physically impaired.[6]

Psychological pain scales

Psychological or self-report pain scales directly capture a child's subjective experience of pain. Interviews, questionnaires, adjective checklists, and numerous pain intensity scales are available for children, each with some evidence of validity and reliability.[1,7] Clinical interviews are ideally suited for learning about the sensory characteristics of pain, the aversive component, and contributing cognitive, behavioral, and emotional factors. Interviews should also include a simple rating scale to document pain strength. Children choose a level on the scale that best matches the strength of their own pain (i.e. a level on a number or thermometer scale, a number of objects, a mark on a visual analogue scale, a face from a series of faces varying in emotional expression, or a particular word from adjective lists). Pain intensity scales are easy to administer, requiring only a few seconds once children understand how to use them. Many of these scales yield pain scores on a 0–10 scale. Visual and colored analogue scales are versatile for use with acute, recurrent, and chronic pain and provide a convenient and flexible pain measure for use in hospital and at home.

Healthcare providers must consider the age and cognitive ability of a child when selecting a pain scale. Most toddlers (approximately 2 years of age) can communicate the presence of pain, using words learned from their parents to describe the sensations they feel when they hurt themselves. They use concrete analogies to describe their perceptions. Gradually children learn to differentiate and describe three levels of pain intensity: 'a little,' 'some or medium,' and 'a lot'. By the age of 5, most children can differentiate a wider range of pain intensities and many can use simple pain intensity scales.

Children's understanding and descriptions of pain naturally depend on their age, cognitive level, and previous pain experience. Children begin to understand pain through their own hurting experiences; they learn to describe the different characteristics of their pains (intensity, quality, duration, and location) in the same way that they learn specific words to describe different sounds, tastes, smells, and colors. Most children can communicate meaningful informa-

tion about their pain. Gradually they develop an increasing ability to describe specific pain features – the quality (aching, burning, pounding, sharp), intensity (mild to severe), duration and frequency (a few seconds to years), location (from a diffuse location on their skin to more precise internal localization), and unpleasantness (mild annoyance to an intolerable discomfort). Children's understanding of pain and the language that they use to describe pain comes from the words and expressions used by their families and peers and from characters depicted in books, videos, and movies. (For a more extensive review of developmental factors in children's pain, see References 8–14.)

Physicians should always ask children directly about their pain. Pain onset, location, frequency (if recurring), quality, intensity, accompanying physical symptoms, and pain-related disability should be assessed as part of children's clinical examination. Healthcare providers should also assess relevant situational factors in order to modify their pain-exacerbating impact, especially the factors listed in Table 9.1.

Table 9.1 Situational factors that increase children's acute pain

Cognitive factors
Lack of age-appropriate information about pain source
Inaccurate expectation of uncontrolled pain
Lack of knowledge about practical non-drug therapies
Lack of choice and little perceived control during treatments
Inaccurate information about child's prognosis
Behavioral factors
Overt physical distress
Inconsistent or inappropriate responses from staff or parents during treatments
Altered parenteral and sibling behaviors toward child within the family
Emotional factors
Anticipatory anxiety toward treatments
Heightened distress during treatments
Fear about continuing pain, increasing disability, or death
Frustration about disruption to activities
Depression about condition or treatments

Pain management

Oral analgesics

Pain control should include regular pain assessments, appropriate analgesics and adjuvant analgesics administered at regular dosing intervals, adjunctive drug therapy for symptom and side-effects control, and non-drug therapies to modify the situational factors that can exacerbate pain and suffering. Analgesics include acetaminophen, non-steroidal anti-inflammatory drugs (NSAIDs), and opioids. Adjuvant analgesics include a variety of drugs with analgesic properties that were initially developed to treat other health problems, such as anticonvulsants and antidepressants. The use of adjuvant analgesics has become a cornerstone of pain control in pediatric chronic pain. They are especially crucial when pain has a neuropathic component.

The guiding principles of analgesic administration are 'by the ladder', 'by the clock', 'by the child', and 'by the mouth'. 'By the ladder' refers to a three-step approach for selecting drugs according to their analgesic potency based on the child's pain level – acetaminophen to control mild pain, codeine to control moderate pain, and morphine for strong pain.[16] The ladder approach was based on our scientific understanding of how analgesics affect pain of nociceptive origin. If pain persists despite starting with the appropriate drug, recommended doses, and dosing schedule, move up the ladder and administer the next more potent analgesic. Even when children require opioid analgesics, they should continue to receive acetaminophen (and NSAIDs if appropriate) as supplemental analgesics. The analgesic ladder approach is based on the premise that acetaminophen, codeine, and morphine should be available in all countries and that doctors and healthcare providers can relieve pain in the majority of children with a few drugs.

However, increasing attention is focusing on 'thinking beyond the ladder' in accordance with our improved understanding of pain of neuropathic origins.[17,18] Children should receive adjuvant analgesics to more specifically target neuropathic mechanisms. Regrettably, two of the main classes of adjuvant analgesics, antidepressants and anticonvulsants, have unfortunate names. Proper education of healthcare providers, parents, and children should lead to a wider acceptance and use of these medications for pain management. For example, amitriptyline may require 4–6 weeks to affect depression, but often requires only 1–2 weeks to affect pain. The newer

classes of antidepressants, the selective serotonin reuptake inhibitors (SSRIs), may be beneficial to treat depression for a child with pain but have not been shown to be beneficial for pain management. The other main class of adjuvant analgesics are the anticonvulsants. The two principal medications used for this purpose in pediatrics are carbamazepine and gabapentin. With gabapentin, the main dose-limiting side effect is sedation, so that a slow titration to maximal dose is required. Because of its greater number of significant side effects, the use of carbamazepine has decreased recently and the use of gabapentin has increased. We still await published studies to support the wide use of gabapentin.

NSAIDs are similar in potency to aspirin. They are used primarily to treat inflammatory disorders and to lessen mild to moderate acute pain. They should be used with caution in patients with hepatic or renal impairment, compromised cardiac function, hypertension (since they may cause fluid retention, edema), and a history of gastrointestinal (GI) bleeding or ulcers. NSAIDs may also inhibit platelet aggregation, and thus must be monitored closely in patients with prolonged bleeding times. NSAIDs have been used for many years in pediatrics and with their minimal side effects, and many advantages (no effect on ventilation, no physical dependence, morphine-sparing effect, etc.), their use should be encouraged.

The specific drugs and doses are determined by the needs of each child. The drugs listed in this chapter are based on guidelines from our institution.[19] Recommended starting doses for analgesic medications to control children's disease-related pain are listed in Table 9.2 and Table 9.3; starting doses for adjuvant analgesic medications to control pain, drug-related side effects, and other symptoms are listed in Table 9.4. (For further review of analgesics and adjuvant analgesics in children, see References 18, 20–23.)

Children should receive analgesics at regular times, 'by the clock', to provide consistent pain relief and prevent breakthrough pain. The specific drug schedule (e.g. every 4 or 6 h) is based on the drug's dura-

Table 9.2 Non-opioid drugs to control pain in children

Drug	Dosage	Comments
Acetaminophen	10–15 mg/kg PO, every 4–6 h	Lacks GI and hematologic side effects; lacks anti-inflammatory effects (may mask infection-associated fever) Dose limit of 65 mg/kg/day or 4 g/day, whichever is less
Ibuprofen	5–10 mg/kg PO, every 6–8 h	Anti-inflammatory activity Use with caution in patients with hepatic or renal impairment, compromised cardiac function or hypertension (may cause fluid retention, edema), history of GI bleeding or ulcers, may inhibit platelet aggregation Dose limit of 40 mg/kg/day; max dose of 2400 mg/day
Naproxen	10–20 mg/kg/day PO, divided every 12 h	Anti-inflammatory activity. Use with caution and monitor closely in patients with impaired renal function. Avoid in patients with severe renal impairment Dose limit of 1 g/day
Diclofenac	1 mg/kg PO, every 8–12 h	Anti-inflammatory activity. Similar GI, renal, and hepatic precautions as noted above for ibuprofen and naproxen Dose limit of 50 mg/dose

Note: Increasing the dose of non-opioids beyond the recommended therapeutic level produces a 'ceiling effect', in that there is no additional analgesia but there are major increases in toxicity and side effects.
IM, intramuscular; PO, by mouth; GI, gastrointestinal.

Table 9.3 Opioid analgesics: usual starting doses for children

Drug	Equianalgesic dose (parenteral)	Starting dose IV	IV:PO ratio	Starting dose PO/ transdermal	Duration of action
Morphine	10 mg	Bolus dose = 0.05 mg/kg–0.1 mg/kg every 2–4 h Continuous infusion = 0.01–0.04 mg/kg/h	1:3	0.15–0.3 mg/kg/dose every 4 h	3–4 h
Hydromorphone	1.5 mg	0.015–0.02 mg/kg every 4 h	1:5	0.06 mg/kg every 3–4 h	2–4 h
Codeine	120 mg	Not recommended		1.0 mg/kg every 4 h (dose limit 1.5 mg/kg/dose)	3–4 h
Oxycodone	5–10 mg	Not recommended		0.1–0.2 mg/kg every 3–4 h	3–4 h
Meperidine[a]	75 mg	0.5–1.0 mg/kg every 3–4 h	1:4	1.0–2.0 mg/kg every 3–4 h (dose limit 150 mg)	1–3 h
Fentanyl[b]	100 µg	1–2 µg/kg/h as continuous infusion		25 µg patch	72 h (patch)

Note: Doses are for opioid-naive patients. For infants under 6 months, start at one-quarter to one-third the suggested dose and titrate to effect.

Principles of opioid administration:
1. If inadequate pain relief and no toxicity at peak onset of opioid action, increase dose in 50% increments.
2. Avoid IM administration.
3. Whenever using continuous infusion, plan for hourly rescue doses with short-onset opioids if needed. Rescue dose is usually 50–200% of continuous hourly dose. If greater than 6 rescues are necessary in 24-h period, increase daily infusion total by the total amount of rescues for previous 24 h/24. An alternative is to increase infusion by 50%.
4. To change opioids – because of incomplete cross-tolerance: if changing between opioids with short duration of action, start new opioid at 50% of equianalgesic dose. Titrate to effect.
5. To taper opioids – anyone on opioids over 1 week must be tapered to avoid withdrawal: taper by 50% for 2 days, and then decrease by 25% every 2 days. When dose is equianalgesic to an oral morphine dose of 0.6 mg/kg/day, it may be stopped. Some patients on opioids for prolonged periods, may require much slower weaning.

[a]Avoid use in renal impairment. Metabolite may cause seizures.
[b]Potentially highly toxic. Not for use in acute pain control.
PO, by mouth; IV, intravenous; IM, intramuscular.

tion of action and the child's pain severity. Although breakthrough pain episodes have been recognized as a problem in adult pain control, they may represent an even more serious problem for children. Unlike adults, who generally realize that they can demand more potent analgesic medications or demand more frequent dosing intervals, children have little control, little awareness of alternatives, and fear that their pain cannot be controlled. They may become progressively frightened, upset, and preoccupied with their symptoms. Thus, it is essential to establish and maintain a therapeutic window of pain relief for children.

Analgesic doses should be adjusted 'by the child'. There is no one dose that will be appropriate for all children with pain. The goal is to select a dose that prevents children from experiencing pain before they receive the next dose. It is essential to monitor the child's pain regularly and adjust analgesic doses as necessary to control the pain. The effective opioid dose to relieve pain varies widely among different children or in the same child at different times. Some children require large opioid doses at frequent intervals to control their pain. If such doses are necessary for effective pain control, and the side effects can be managed by adjunctive medication so that children are comfortable, then the doses are appropriate. Children receiving opioids may develop altered sleep patterns so that they are awake at night, fearful and complaining about pain, and they sleep intermittently throughout the day. They should receive adequate

Table 9.4 Adjuvant analgesics: doses for children

Drug category	Drug, dosage	Indications	Comments
Antidepressants	Amitriptyline, 0.2–0.5 mg/kg PO Titrate upward by 0.25 mg/kg every 2–3 days. Maintenance: 0.2–3.0 mg/kg Alternatives: nortriptyline, doxepin, imipramine	Neuropathic pain (i.e. vincristine-induced, radiation plexopathy, tumor invasion, CRPS-1) Insomnia	Usually improved sleep and pain relief within 3–5 days Anticholinergic side effects are dose-limiting. Use with caution for children with increased risk for cardiac dysfunction
Anticonvulsants	Gabapentin, 5 mg/kg/day PO Titrate upward over 3–7 days. Maintenance: up to 15–50 mg/kg/day PO divided tid. Carbamazepine, Initial dosing: 10 mg/kg/day PO divided od or bid. Maintenance: up to 20–30 mg/kg/day PO divided every 8 h. Increase dose gradually over 2–4 weeks Alternatives: phenytoin, clonazepam	Neuropathic pain, especially shooting, stabbing pain	Side effects: gastro-intestinal upset, ataxia, dizziness, disorientation, somnolence Monitor for hematologic, hepatic, and allergic reactions with carbamazepine
Sedatives, hypnotics, anxiolytics	Diazepam, 0.025–0.2 mg/kg PO every 6 h Lorazepam, 0.05 mg/kg/dose SL Midazolam, 0.5 mg/kg/dose PO administered 15–30 min prior to procedure; 0.05 mg/kg/dose IV for sedation	Acute anxiety, muscle spasm Premedication for painful procedures	Sedative effect may limit opioid use. Other side effects include: depression and dependence with prolonged use
Antihistamines	Hydroxyzine, 0.5 mg/kg PO every 6 h Diphenhydramine, 0.5–1.0 mg/kg PO/IV every 6 h	Opioid-induced pruritus, anxiety, nausea	Sedative side effects may be helpful
Psychostimulants	Dextroamphetamine, methylphenidate, 0.1–0.2 mg/kg bid Escalate to 0.3–0.5 mg/kg as needed	Opioid-induced somnolence Potentiation of opioid analgesia	Side effects include agitation, sleep disturbance, and anorexia Administer second dose in afternoon to avoid sleep disturbances
Corticosteroids	Prednisone, prednisolone, and dexamethasone dosage depends on clinical situation (i.e. dexamethasone initial dosing: 0.2 mg/kg IV. Dose limit 10 mg. Subsequent dose 0.3 mg/kg/day IV divided every 6 h)	Headache from increased intracranial pressure, spinal or nerve compression; widespread metastases	Side effects include edema, dyspeptic symptoms, and occasional gastro-intestinal bleeding

CRPS-1 = complex regional pain syndrome, type 1; PO, by mouth; IV, intravenous; SL, sublingual; tid, three times daily; bid, twice day; od, once daily.
Modified from McGrath and Brown.[20]

analgesics at night with antidepressants or hypnotics as necessary to enable them to sleep throughout the night. To relieve ongoing pain, opioid doses should be increased steadily until comfort is achieved, unless the child experiences unacceptable side effects such as somnolence or respiratory depression (Table 9.5).

'By the mouth' refers to the oral route of drug administration. Medication should be administered to children by the simplest and most effective route, usually by mouth. Since children are afraid of painful injections they may deny that they have pain or they may not request medication. When possible, children should receive medications through routes that do not cause additional pain. Although optimal analgesic administration for children requires flexibility in selecting routes according to children's needs, parenteral administration is often the most efficient route for providing direct and rapid pain relief. Since intravenous, intramuscular, and subcutaneous routes cause additional pain for children, serious efforts have been expended on developing more pain-free modes of administration that still provide relatively direct and rapid analgesia. Attention has focused on improving the effectiveness of oral routes. As an example, oral transmucosal fentanyl citrate (OTFC) provides rapid-onset analgesia via a pleasant route for children receiving painful medical procedures. OTFC produces significant serum concentrations after 15–20 minutes.[24] Children aged 2–14 years have shown good cooperation and sedation when given OTFC as a premedication.[25,26] OTFC produced safe and effective analgesia for outpatient wound care in

Table 9.5 Opioid side effects

Side effect	Management
Respiratory depression	Reduction in opioid dose by 50%, titrate to maintain pain relief without respiratory depression
Respiratory arrest	Naloxone, titrate to effect with 0.01 mg/kg/dose IV/ETT increments or 0.1 mg/kg/dose IV/ETT, repeat prn. Small frequent doses of diluted naloxone or naloxone drip preferable for patients on chronic opioid therapy to avoid severe, painful withdrawal syndrome. Repeated doses often required until opioid side effect subsides
Drowsiness/sedation	Frequently subsides after a few days without dosage reduction; methylphenidate or dextroamphetamine (0.1 mg/kg administered twice daily, in the morning and mid-day so as not to interfere with night-time sleep). The dose can be escalated in increments of 0.05–0.1 mg/kg to a maximum of 10 mg/dose for dextroamphetamine and 20 mg/dose for methylphenidate
Constipation	Increased fluids and bulk, prophylactic laxatives as indicated
Nausea/vomiting	Administer an antiemetic (e.g. ondansetron, 0.1 mg/kg IV/PO every 8 h) Antihistamines (e.g. dimenhydrinate 0.5 mg/kg/dose every 4–6 h IV/PO) may be used. Prechemotherapy, nabilone 0.5–1.0 mg PO and then every 12 h may also be used
Confusion, nightmares, hallucinations	Reassurance only, if symptoms mild. A reduced dosage of opioid or a change to a different opioid or add neuroleptic (e.g. haloperidol 0.1 mg/kg PO/IV every 8 h to a maximum of 30 mg/day)
Multifocal myoclonus; seizures	Generally occur only during extremely high-dose therapy; reduction in opioid dose indicated if possible. Add a benzodiazepine (e.g. clonazepam 0.05 mg/kg/day divided bid or tid increasing by 0.05 mg/kg/day every 3 days prn up to 0.2 mg/kg/day. Dose limit of 20 mg/day)
Urinary retention	Rule out bladder outlet obstruction, neurogenic bladder, and other precipitating drug (e.g. tricyclic antidepressant). Particularly common with epidural opioids. Change of opioid, route of administration, and dose may relieve symptom. Bethanechol or catheter may be required

IV, intravenous; PO, by mouth; ETT, endotracheal tube; prn, as needed; bid, twice a day; tid, three times a day. Reprinted with permission from McGrath and Brown.[20]

children and the taste was preferred to oral oxycodone.[27]

Many hospitals have restricted the use of intramuscular injections because they are painful and drug absorption is not reliable; they advocate the use of intravenous lines into which drugs can be administered directly without causing further pain. Topical anesthetic creams should also be applied prior to the insertion of intravenous lines in children. The use of portacatheters has become the gold standard in pediatrics, particularly for children with cancer under the care of the urologist, who require administration of multiple drugs at weekly intervals.

Continuous infusion has several advantages over intermittent subcutaneous, intramuscular, or intravenous routes. This method circumvents repetitive injections, prevents delays in analgesic drug administration, and provides continuous levels of pain control without children experiencing increased side effects at peak level and pain breakthroughs at trough level. Continuous infusion should be considered when children have pain for which oral and intermittent parenteral opioids do not provide satisfactory pain control, when intractable vomiting prevents the use of oral medications, and when intravenous lines are not desirable. Children receiving a continuous infusion should continue to receive 'rescue doses' to control breakthrough pain, as necessary. As outlined in Table 9.3, the rescue doses should be 50–200% of the continuous infusion hourly dose. If children experience repeated breakthrough pain, the basal rate can be increased by 50% or by the total amount of morphine administered through the rescue doses over a 24-h period (divided by 24 h).

Patient-controlled analgesia

Patient-controlled analgesia (PCA) enables children to administer analgesic doses according to their pain level. PCA provides children with a continuum of analgesia that is prompt, economical, not nurse dependent, and a lower overall narcotic use.[28–31] It has a high degree of safety, allows for wide variability between patients, and there is no delay in analgesic administration. (For review, see Reference 32.) It can now be regarded as a standard for the delivery of analgesia in children aged >5 years old.[33] However, there are opposing views about the use of background infusions with PCA. Although they may improve efficacy, they may increase the occurrence of adverse effects such as nausea and respiratory depression. In a comparison of PCA with and without a background infusion for children having lower extremity surgery, the total morphine requirements were reduced in the PCA-only group and the background infusion offered no advantage.[34] In another study comparing background infusion and PCA, children between 9 and 15 years old achieved better pain relief with PCA, whereas children between 5 and 8 years old showed no difference.[35] Our current standard is to add a background infusion to the PCA if the pain is not controlled adequately with PCA alone. The selection of opioid used in PCA is perhaps less critical than the appropriate selection of parameters such as bolus dose, lockout, and background infusion rate. The opioid choice may be based on an adverse-effect profile rather than on efficacy. Clearly, patient-controlled analgesia offers special advantages to children who have little control and who are extremely frightened about uncontrolled pain. PCA is, as it states, patient-controlled analgesia: when special circumstances require that other people administer the medication, we do allow both nurse- and parent-controlled analgesia. Under these circumstances, parents require our nurse educators to fully educate them on the use of PCA. A recent alert by the Joint Commission on Accreditation of Health Care Organizations (JCAHO) advised that serious adverse events can result when family members, caregivers, or clinicians who are not authorized become involved in administering the analgesia for the patient 'by proxy'.[36,37]

Transdermal fentanyl

Fentanyl is a potent synthetic opioid, which like morphine binds to mu (μ) receptors. However, fentanyl is 75–100 times more potent than morphine. The intravenous preparation of fentanyl has been used extensively in children. A transdermal preparation of fentanyl was introduced in 1991 for use with chronic pain. This route provides a non-invasive but continuously controlled delivery system. Although limited data are available on transdermal fentanyl (TF) in children, its use is increasing for children with pain. In a 2001 study, TF was well tolerated with effective pain relief in 11 of 13 children and provided an ideal approach for children where compliance with oral analgesics was problematic.[38] In another study, when children were converted from oral morphine doses to TF; the investigators noted diminished side effects and improved convenience with TF.[39] The majority of parents and investigators considered TF to be better than previous treatment. No serious adverse events were attributed to fentanyl, suggesting that TF

was both effective and acceptable for children and their families. Similarly, no adverse effects were noted in a study of TF for children with pain due to sickle cell crisis.[40] This study showed a significant relationship between TF dose and fentanyl concentration; pain control with the use of TF was improved in 7 of 10 patients in comparison to PCA alone. In a multicenter crossover study in adults, TF caused significantly less constipation and less daytime drowsiness in comparison to morphine, but greater sleep disturbance and shorter sleep duration.[41] Of those patients able to express a preference, significantly more preferred fentanyl patches. As with all opioids, fatal adult complications have been noted with the use of multiple transdermal patches.[42]

Regional anesthesia

Topical

Topical anesthetics have proved invaluable in assisting with not only decreasing pain for minor procedures such as intravenous insertion but also for some procedures that are more invasive. At the Hospital for Sick Children, a number of these topical anesthetics are employed and include EMLA (lidocaine/prilocaine cream), Ametop (tetracaine hydrochloride), or Maxilene 4 (lidocaine cream). Each of these agents has advantages and disadvantages – EMLA requires approximately 1 hour to onset and causes vasoconstriction compared with Ametop, which is quicker in onset at approximately 30 minutes. Maxilene 4 has the advantage of being effective in approximately 10 minutes and does not require an occlusive barrier with application.

EMLA has been shown to be an effective and simple method to produce postcircumcision analgesia,[43] is simple to use, and avoids the rare but serious complications of a dorsal penile nerve block. A meta-analysis of three randomized controlled trials using EMLA prior to circumcision demonstrated a statistically significant reduction in pain.[44]

Local infiltration

The surgeon or the anesthesiologist should not underestimate the importance of postoperative pain relief. One of the simplest methods of postoperative analgesia is local infiltration of the wound with a long-acting local anesthetic such as bupivacaine. The adult literature is confusing at times, with various reports showing either a benefit or showing no demonstrative positive results. On the other hand, the pediatric literature is quite clear on the benefits of local infiltration. Beginning in the 1980s, two different studies were reported in the journal *Anaesthesia*: the first report compared wound infiltration to the use of the ilioinguinal nerve block[45] and the second report compared wound infiltration to the caudal block.[46] Wound infiltration provided comparable results to both the ilioinguinal and caudal block. In the 1990s, two more studies compared wound infiltration again to the caudal block[47] and to an ilioinguinal/iliohypogastric block.[48] The results were similar as to before, with wound infiltration providing satisfactory analgesia. Bupivacaine is our standard local anesthetic for this type of procedure at the Hospital for Sick Children, but this is not the important point. Doing the block is!

Peripheral nerve blockade

Two of the most commonly used blocks performed by the urologist are the penile block and the ilioinguinal and iliohypogastric nerve block. Both blocks are safe, easy to learn and perform, and provide good analgesia.

The penile block provides excellent analgesia, and is especially useful for the commonly performed circumcision. The penile block is easily learned by residents,[49] with over a 90% success rate possible in the first 10 blocks performed. The subpubic approach is preferred: a short-bevel needle is inserted 0.5–1 cm lateral to the midline, bilaterally into the subpubic space (deep to Scarpa's fascia), where the nerves run before entering the base of the penis, and a small volume of local anesthetic (0.1 ml/kg of body weight – usually 1–2 ml per side) is injected. Dalens et al[50] achieved a 100% success rate on 100 patients employing this technique. Our preferred local anesthetic is 0.5% bupivacaine, without epinephrine. For a full description of the technique see Reference 51. An alternative approach is the subcutaneous ring block of the penis. In a prospective study[52] it was shown that the penile block provided significantly better analgesia than the subcutaneous block.

The other commonly performed block is the ilioinguinal/iliohypogastric nerve block. This block is especially useful for procedures such as inguinal herniorrhaphy, hydrocele, and orchiopexy. The goal of this block is to anesthetize the ilioinguinal, iliohypogastric, and the genital branch of the genitofemoral nerve. A short-bevel needle is employed and is inserted 1 cm medial and 1 cm inferior to the anterior superior iliac spine. The needle is inserted through

skin, external oblique, and the internal oblique muscles. The local anesthetic is then inserted in a fan-shaped motion as well as a subcutaneous wheal. I personally use 0.2–0.4 ml/kg of 0.25% bupivacaine with 1:200 000 epinephrine (to a maximum dose of 10 ml). These volumes have to be adhered to strictly because of the possibility of increased bupivacaine concentrations after ilioinguinal block in pediatric patients.[53] For an excellent description of this procedure see Reference 51. The ilioinguinal/iliohypogastric block compares favorably with the caudal block, as confirmed by a prospective comparative study from 1986 which demonstrated that both blocks provide excellent postoperative analgesia.[54]

Caudal epidural blocks

The caudal approach to the epidural space is one of the most frequently used approaches to provide anesthesia and postoperative analgesia for the pediatric urology patient. Easy access to the caudal space can be made at the level of the sacrococcygeal ligament, thus reducing the risk of neurologic injury. There are well-known variations to the sacral hiatus though,[55] and thus if after several attempts at placing a caudal block you are unsuccessful, alternative methods of analgesia must be found. The procedure is performed frequently on our patients at the Hospital for Sick Children for cases such as herniorrhaphy and orchiopexy and for most hypospadias repairs. With the ease of procedure, good safety profile, and the excellent results it provides, it seems logical that it remains one of our gold standards. In a 1989 retrospective study of caudal analgesia in 750 pediatric patients, Dalens and Hasnaoui found no major complications or neurologic sequelae, and good patient and parent acceptance of caudal anesthesia. Their overall success rate was 96%, with most failures occurring in children >7 years old.[56] Although the addition of preoperative or postoperative acetaminophen showed no increased effect on the duration and intensity of postoperative analgesia obtained by caudal bupivacaine,[57] we continue to recommend its use perioperatively in a dosage of 30–40 mg/kg given as a rectal suppository. In some cases that may have a prolonged surgical time or that may require admission of the patient to hospital, a catheter may be left in place that can be 'topped up' by the anesthesiologist at the end of the case. Alternatively, this catheter may be employed to run an infusion in a manner similar to a formal epidural. In a recent study, both caudal and epidural analgesia combined with intravenous rescue analgesics provided adequate pain control following intravesical ureteroneocystostomy.[58]

Epidural and spinal analgesia

The use of regional techniques (epidural and spinal) for the administration of local anesthetics and analgesics for children continues to be an integral part of pain control in children.[59] Experience from many centers suggests that these techniques can be extremely useful for children undergoing extensive surgery with resulting pain that may be difficult to control by more conventional means.

When one undertakes the administration of potent analgesics and anesthetics, whether by intravenous or a regional anesthetic technique such as an epidural or spinal approach, appropriate monitoring is paramount for the safety of the patient. This involves:

- the education and training of staff
- the immediate availability of resuscitative drugs and equipment
- an accurate and timely pain record, consisting of vitals signs, pain, and sedation scores.

A complete set of intravenous and epidural monitoring guidelines is shown in Table 9.6.

Complementary/alternative therapies

An extensive array of non-drug therapies are available to treat children's pain, including counseling, guided imagery, hypnosis, biofeedback, behavioral management, acupuncture, massage, homeopathic remedies, naturopathic approaches, and herbal medicines. In a 2002 self-report questionnaire of 1013 pediatric patients seeking primary care, the most common types of complementary/alternative therapies (CAM) were herbs (41%), prayer healing (37%), folk/home remedies (28%), massage therapy (19%), and chiropractic (18%).[60] Non-drug therapies are generally regarded as safe, with few contraindications for their use in otherwise healthy children. However, little is known about the safety and effectiveness of certain therapies for children. The problem of major adverse events and the high degree of uncertainty regarding a causal relationship of these events and the therapy is frequently noted. The size of the problem and its importance relative to the well-documented risks of conventional treatments is presently unknown.[61] Although Sampson et al[62] reported 908 randomized controlled trials (RCTs) in the field of CAM and Moher et al[63] have assessed the quality of 47 CAM systematic reviews, where they found the overall qual-

Table 9.6 Analgesia monitoring guidelines

Baseline assessment
Obtain RR, HR, BP, O_2 saturation, sedation score, and pain score before administering a single or intermittent dose or initiating continuous infusion

Intermittent intravenous administration
RR, HR, BP, and sedation score every 5 min × 4, then every 30 min × 2, and then as per child's condition/pre-existing orders
Pain score every 20–30 min
Continuously monitor O_2 saturation only for children whose underlying condition predisposes them to respiratory depression

Intravenous additive (to run over 15–20 min)
RR, HR, BP, and sedation score every 10 min × 2, then every 30 min × 2, and then as per child's condition
Pain score at completion of the flush, then every 30 min × 2, and then as per child's condition/pre-existing orders
Continuously monitor O_2 saturation only for children whose underlying condition predisposes them to respiratory depression

Continuous IV infusion/PCA
RR, HR, BP, pain score, and sedation score every 1 h × 4, then RR and sedation score every 1 h, and then HR, BP, and pain score every 4 h
Continuously monitor O_2 saturation and document reading every 1 h

Intermittent epidural administration
RR, HR, and BP every 5 min for the first 20 min following a bolus dose, and then RR and sedation score every 1 h
HR, BP, pain score, and motor block score every 4 h
Continuously monitor only for children whose underlying condition predisposes them to respiratory depression

Continuous epidural infusion[a,b]
RR, HR, BP, sedation score, pain score and motor block score every 1 h × 4 h, then RR and sedation score every 1 h, and HR, BP, pain score, and motor block score every 4 h
Continuously monitor O_2 saturation and document reading every 1 h

[a] Opioids used with bupivacaine.
[b] **Note:** After any change in drug dose, infusion rate, or if transferred between patient care areas, return to assessments every 1 h for 4 h.
Continuous respiratory rate/apnea monitoring may provide additional benefits for certain children who are receiving continuous opioid infusions by alerting the nurse to a decreasing respiratory rate. Respiratory rate monitoring is not, however, a substitute for frequent patient observation and vital sign monitoring.
ECG monitoring is not routinely required, but may be ordered if the child's underlying condition predisposes them to ECG abnormalities.
RR, respiratory rate; HR, heart rate; BP, blood pressure; ECG, electrocardiogram.

ity of reporting similar to conventional therapy, researchers continue to call for more studies in this area.[64] Thus, the efficacy of complementary therapies for treating children's pain is unclear, even though children are increasingly using complementary therapies.[65] Madsen et al[66] reported in 2003 that 53% of pediatric patients had tried CAM as a supplement to conventional medicine, which compares with an Australian study of 33% of parents having used CAM for their inpatient child.[67] The percentages were even higher for children with cancer using CAM (65%) compared with a control group (51%).[68]

Cognitive and behavioral methods of pain management

Cognitive and behavioral therapies can mitigate some of the factors that intensify pain, distress, and disability for children. In contrast to complementary therapies, the evidence base supporting the efficacy of

cognitive and behavioral approaches is strong.[15,28,69–81] Cognitive therapies are directed at a child's beliefs, expectations, and coping abilities. They encompass a wide range of approaches from basic patient education to formal psychotherapy. Most children and families benefit from supportive counseling. Accurate information about what will happen and what children may feel should improve children's understanding, increase their control, lessen their distress, and reduce their pain. In addition, healthcare providers can teach children how to use a few pain control methods to lessen pain and guide families to recognize the particular circumstances that exacerbate pain and distress. These methods provide children with some independent strategies – either to relieve mild pain or to complement the medication needed to relieve strong pain. Children seem more adept than adults at using non-drug therapies, presumably because they are usually less biased than adults about their potential efficacy.

Distraction is a simple and effective pain control method. When children intently attend to something other than their pain, they can lessen its intensity and unpleasantness. Distraction is often incorrectly perceived as a simple diversionary tactic; the implication is that the pain is still there but the child is momentarily focused elsewhere. However, when children's attention is fully absorbed in some engaging topic or activity, distraction is a very active process that can reduce the neuronal responses to a noxious stimulus. Children do not simply ignore their pain, but are actually reducing it. The essential feature for achieving pain relief is a child's ability to attend fully to and concentrate on something else besides the pain. Therefore, the choice of a distraction is crucial and varies according to children's ages and interests. Young children usually need to be actively involved with their parents or peers, whereas older children and adolescents can distract themselves more independently. Children should work with their parents or a therapist to choose distracting activities that they can practically incorporate into their lives.

There is considerable overlap among the interventions of attention/distraction, guided imagery, and hypnosis. Hypnosis usually begins with an induction procedure in which a child's full attention is focused gradually on the therapist and his/her suggestions. The therapist guides the child into a very relaxed physical and mental state, an altered level of consciousness – distinct from an alert or sleep state. The induction procedure typically includes guided imagery for the child and progressive muscle relaxation for the adolescent. The induction can be very simple for young children. They can be guided into an hypnotic state as they vividly imagine their favorite television shows, movies, books, or cartoon characters.[82–84] As they imagine an activity, scene, or character, they gradually receive suggestions for relaxation, reduced anxiety, increased control, and pain reduction. The therapist provides consistent positive suggestions, rather than authoritative commands. The emphasis is on the child's own natural abilities, as in, 'Notice that your back, legs (painful body areas) feel lighter, the heaviness and pain are starting to lessen. It seems as if your back doesn't hurt as much as before. You are doing well at turning down the pain switch.'

During an hypnotic state, individuals become extremely susceptible to suggestions, including suggestions for pain relief. Children become so involved in thoughts or ideas that they dissociate from a 'reality orientation'.[83] Hypnosis enables children to redirect attention from the painful sensation or to reinterpret the sensation as something more pleasant/less aversive and/or less bothersome.[84] Like adults, children differ in their ability to be hypnotized. Children's ability to use their imagination is the key component in determining their hypnotic susceptibility.

Behavior therapy is often used in combination with cognitive therapy. The goals are to lessen the specific behaviors (i.e. child, family, and staff) that may increase pain, distress, or disability, while concomitantly increasing healthy behaviors that engage children in living as fully as possible. Relaxation training is a common method used for children who require painful procedures or who experience chronic pain. Therapists train children how to achieve a state of mental and physical relaxation, so that those children can eventually relax independently when they experience pain or feel stressed and fearful about their condition. Therapists may use guided imagery, hypnosis, deep breathing, or progressive relaxation exercises to train children.

Conclusion

In this chapter we have briefly reviewed the management of pain for the pediatric patient as it applies to the urologist. In surveys carried out at the Hospital for Sick Children in Toronto and elsewhere, the assessment and management of pain in our patients was inadequate in the past and continues to this day. A full multidisciplinary 'pain team' that involves all

the techniques and skills of the anesthesiologist perioperatively and the pain team postoperatively is essential. The day when intramuscular Demerol (meperidine) could end pain and suffering is surely over. The pharmacologic and non-pharmacologic tools that we now have in our pain armamentarium must be used to end pain in our patients.

Office pediatric urology

10

Patrick C Cartwright, Timothy A Masterson, and Brent W Snow

Introduction

The environment of a medical office can play a pivotal role in making pediatric patients and their families comfortable. Engaging decorations, bright colors, toys, and play areas often help calm nervous children. A bulletin board with patient photos and cards may soften the feel of the office. Every effort should be made to allow parents to be with their child at all times to provide reassurance. Each physician's style and personality is different, but often those who deal with children forego the formality of a white coat so that the encounter might be more familiar to the patient. It is important upon entering the examination room first to engage the patient in gentle conversation, when possible, to develop rapport and place the child at ease. If the child is old enough, history taking generally begins with the child and is supplemented by parental input.

The physical examination is generally performed on the examining table with a parent standing beside the physician at the head of the bed. It is important to let the child know that he will not be poked or hurt but gently checked. As children approach puberty, they may be relieved to have one or both of their parents leave for the examination when given this opportunity by the physician. After the examination is completed, it is important to let patients know that they are finished so they will no longer be ill at ease. Upon leaving the office, children are often rewarded for their good behavior so that they will look forward to return visits.

Most physicians find that dealing with children in an honest, straightforward manner is best. It is appropriate to tell the child before any uncomfortable procedures are undertaken to develop trust in the provider. Surprising a child with an unpleasant examination or injection results in a loss of trust and faith in the physician, which is difficult to regain. Parents are encouraged to tell their children honestly about diagnostic X-ray examinations and office visits so that the children can be appropriately prepared. Under these circumstances, the examination and history may be completed accurately with little threat to the child.

The penis

Foreskin and phimosis

The appropriate management of penile problems in childhood is based upon an understanding of genital embryology and postnatal penile development. Genital differentiation takes place between the 9th and 13th weeks of gestation. The glans penis forms from the genital tubercle and is covered with a prepuce which is adherent to its surface. The preputial attachments persist throughout gestation and the epithelial layer of the inner prepuce and the glans penis are fused at birth. The newborn foreskin cannot be retracted without disrupting this natural adherence. Subsequently, glandular secretions and desquamated epithelial debris, collectively called smegma, collect between the inner prepuce and the glans penis, gradually separating these two layers. The build up of this material can be impressive and patients may present with a mass that can be seen through the thin foreskin. This has been referred to as a foreskin pearl. Treatment is not required as the smegma eventually erupts at the foreskin meatus, disrupting the adherence and resulting in partial separation of the foreskin.[1] This sequence is often misdiagnosed as a penile infection, with the smegma presumed to be 'pus'. Reassurance usually quiets parental concerns.

The physiologic adherence (physiologic phimosis) resolves spontaneously, but may remain present for several years. Texts suggest that most physiologic phimosis resolves by the age of 3–5 years, such that the glans penis can be fully exposed.[2] In the authors' experience, limited adherence of little significance may remain for years longer. In a longitudinal study, Oster[3] reported that physiologic phimosis in school-aged boys resolved over time (Table 10.1).

Physiologic phimosis should be distinguished from

Table 10.1 Incidence of phimosis in children

Age (years)	Phimosis (%)	Tight prepuce (%)
6–7	8	1
8–9	6	2
10–11	6	2
12–13	3	3
14–15	1	1
16–17	1	1

pathologic or true phimosis. Physiologic phimosis exists when the adherence between the inner prepuce and glans penis persists as filmy attachments. True phimosis occurs when the foreskin cannot be retracted after it has been previously retractable, if there is a densely thickened prepuce that will not retract, or one that remains non-retractile after a patient has completed pubertal development.

The easiest way to differentiate physiologic phimosis from pathologic phimosis is careful examination. Forceful separation of foreskin adhesions is not recommended because of pain and trauma to the patient, but gentle proximal traction of the foreskin may enable one to differentiate between normal and abnormal. If the foreskin retracts part way and then lays flat against the glans penis and effaces or thins, the remaining attachments are probably physiologic and more time is required for natural separation to occur. If, when the foreskin is retracted to the point of attachment there is a thickened, rolled edge, this is likely pathologic phimosis due to scarring and inflammation (Figure 10.1). This is unlikely to resolve spontaneously and may require circumcision. Ballooning of the foreskin during voiding is often associated with true phimosis as well. There have been recent studies suggesting that steroids applied to the prepuce and glans penis will help separate physiologic adhesions, aiding in the resolution of this diagnostic dilemma.[4]

Questions often arise about care of the uncircumcised penis. The genital area should be cleaned as any other skin area and the foreskin may be gently retracted to the extent allowable without discomfort for cleaning. Forcible retraction may result in tearing of the foreskin meatus, inflammation, and secondary scarring leading to true phimosis.

Postcircumcision phimosis (entrapped penis)

Following routine neonatal circumcision with any standard circumcision clamp, an unusual type of

Figure 10.1 This prepuce displays a true 'phimotic ring' laterally and inferiorly with thickened skin, whereas superiorly the skin shows a more normal, effaced (thin) appearance when the foreskin is pushed gently toward the base of the penis.

secondary phimosis can develop. Since the circumcision scar is circumferential, and the process of wound healing involves contracture, this may cause narrowing of the shaft skin at the circumcision site. If the circumcision site is mobile and sufficient inner foreskin remains, the circumcision site can migrate distally over the glans and begin to contract in this position (Figure 10.2). This contraction and scarring may be tight enough that the glans penis can no longer be seen and occasionally urinary flow may be restricted. This type of phimosis (penile entrapment, secondary phimosis) can be avoided by firmly seating the bell of the newborn clamp at the coronal margin so that there is no redundant inner prepuce remaining which might let the circumcision scar ride distally over the coronal margin. This seems to be a more common problem in young boys with an abundant pubic fat pad who may not be candidates for circumcision in the first place (Figure 10.3). If secondary phimosis is discovered early after circumcision, aggressive fore-

Figure 10.2 Entrapped penis following circumcision (secondary phimosis).

Figure 10.3 Severe penile entrapment. This required incision of the phimotic ring in two locations followed by horizontal closure of the vertical incision lines.

skin retraction by stretching the ring with a hemostat dilates the scar and the need for later revision of the circumcision is avoided. In other cases, the phimotic ring may be anesthetized and snipped in the office, incising vertically and closing horizontally to create a wider circumference. This may not resolve the problem in all patients and formal circumcision revision may be necessary in some, reducing the inner foreskin length so that the circumcision scar cannot migrate past the coronal margin; occasionally, removal of more shaft skin becomes necessary.

Penile glanular adhesions (skin bridges)

After newborn circumcision, the glans epithelium is denuded owing to separation of the physiologic adhesions with the foreskin. The circumcision site is also a raw surface and if the glans epithelium and the circumcision site rest together for a prolonged period, a postsurgical adhesion may form (Figure 10.4). These are dense adhesions that cannot be teased apart in the office. These adhesions usually occur as skin bridges so that an instrument tip can be passed underneath them, and their blood supply comes from both the shaft skin and the glans. Surgical division of such skin bridges is required.

This technique usually requires some sort of analgesic agent, which may be EMLA® cream, or local injection in the office, or if more extensive, general anesthesia. After appropriate analgesia, a hemostat is used to crush the bridge near the glans and the adhesion is divided with scissors, rotating the blade and cutting the skin bridge nearly flush with the glans epithelium. Sometimes a second cut flush with the shaft skin will be necessary for good cosmesis. It is important not to cut the skin bridge in the middle because this often leaves a skin tag of shaft skin on the glans penis, which is a noticeable cosmetic problem. Suturing may be necessary for bleeding or wound approximation. Ointment is then placed on the penis twice daily for 7–10 days; gently retracting the shaft skin prevents the two edges from coming into contact to reform the adhesion.

Figure 10.4 Postcircumcision skin bridges.

Paraphimosis

Paraphimosis is the term applied when the foreskin has been retracted and cannot then be brought back over the glans penis (Figure 10.5). This can happen after the foreskin has been forcefully separated for the first time, disrupting the preputial adherence to the glans. In the hospital this often occurs when the foreskin has been retracted for the placement of an indwelling catheter. Once the catheter has been secured, medical personnel neglect to replace the foreskin over the glans penis. With the tight foreskin proximal to the glans penis, venous congestion leads to progressive swelling. When paraphimosis is recognized, it is imperative that the foreskin be immediately placed back over the glans to allow the blood flow to return to the prepuce and glans. If there is significant edema, this can be difficult. The best technique is to hold a gauze sponge with the index and third fingers of each hand proximal to the foreskin, with the gauze covering the fingers for traction. The thumbs push the glans penis back through the paraphimotic ring between the other four fingers that are supporting it. A minute or two of steady pressure may be required to decompress the glans and force the foreskin edema proximally and allow for the glans to suddenly slip through to the paraphimotic ring. Placing ice on the penis before this procedure has been advocated and a penile anesthetic block may be administered before the manual reduction. Additionally, infiltration of the edematous foreskin with hyaluronidase has been reported to facilitate decompression.[5] If manual reduction is unsuccessful, immediate dorsal slit of the tight preputial ring will restore venous drainage from the distal tissue. A formal circumcision can be completed at a later date if necessary.

Figure 10.5 Paraphimosis with edematous, discolored prepuce trapped proximal to glans penis.

Meatal stenosis

Stenosis of the urethral meatus seems to be largely an acquired problem of circumcised boys. Recurrent meatitis or meatal inflammation secondary to prolonged exposure of the meatus to the moist and irritating environment of the diaper (ammoniacal dermatitis) or other inflammatory skin diseases can induce this problem. The delicate meatal skin edges lose their superficial epithelial lining when inflamed, and as a result become adherent in a side-to-side fashion. This almost always occurs ventrally and progresses dorsally, and boys are left with a small or even pinpoint meatus at the apex of the glans. Some authors have suggested that the advent of disposable diapers has led to increasing prevalence of this problem since the 1980s. The occurrence of meatal stenosis is distinctly unusual in an uncircumcised boy and therefore is best considered a potential side-effect of circumcision.

Causes beyond simple irritation which can induce strictures of the meatus include prior hypospadias repair or other penile surgery, prolonged urethral catheterization, trauma, or balanitis xerotica obliterans (BXO). These diagnoses are often apparent on examination or when reviewing the child's history. BXO induces a characteristic whitish circumferential discoloration of much of the glans and may induce a narrowing of the urethra extending more proximal than simple irritative meatal stenosis. BXO is more difficult to treat.

Normal meatal caliber based on age has been reported in boys. In general, a boy under the age of 1 year should have a meatus that easily accepts a 5 Fr feeding tube. Between the ages of 1 and 6 years this increases to at least an 8 Fr size. It can be difficult to estimate meatal size accurately when inspecting this visually. However, gentle lateral traction on the meatal edges to open the meatus side to side reveals the typical fused appearance of the ventral edges, confirming some degree of stenosis. On the other hand, if normal urethral mucosa can be everted, meatal size is probably adequate. Final confirmation is obtained by observing voiding. There is a characteristic dorsal deflection of the stream due to a ventral lip of scar tissue as a result of fusion of the meatal edges. The patient also demonstrates a very fine-caliber, forceful stream with a long voiding distance. This is due to the acute decrease in the size of the lumen of the urethra distally and the secondary accelerated velocity of the urine. Some patients will learn to direct their penis towards their feet during voiding so that the stream will enter the toilet bowl, whereas others seem not to catch on and miss the bowl entirely.

Meatal stenosis is uncommonly diagnosed prior to a boy becoming toilet trained. There may be intermittent dysuria with discomfort at the tip of the glans and occasional blood spotting in the underwear due to recurrent inflammation at the meatus. Patients with meatal stenosis demonstrate a prolonged voiding time and some boys decide that it is simpler to sit during voiding rather than try to direct their streams while standing. It should be noted that meatal stenosis is an unlikely cause of recurring urinary tract infection (UTI) or true obstruction to the lower urinary tract. When the history, examination, and observation of the urinary stream suggest meatal stenosis, no other diagnostic evaluation is required.

When any of the above symptoms are present, and voiding is characteristic, treatment of meatal stenosis is generally warranted. Simple dilatation of the urethral meatus will often result in tearing of the skin edges and a high rate of recurrent stenosis. Urethral meatotomy is, therefore, the preferred method of treatment. Meatotomy is a very simple procedure in which one prong of a hemostat is inserted within the urethral meatus and directed toward the ventrum in the midline of the glans a few millimeters proximal to the stenotic pinpoint meatus. The skin edges are crushed together for 1–2 minutes. Once the clamp is removed, fine scissors are used to incise the ventral midline, thus reopening the meatus (Figure 10.6). The crushed skin remains together, generating appropriate hemostasis.

Options exist in terms of anesthetic techniques for meatotomy. The procedure may be performed under a general anesthetic in the operating room as a quick and simple outpatient procedure; however, this is generally not necessary. Some urologists have performed this procedure in an office setting by injecting a small amount of lidocaine with epinephrine directly into the ventral meatal skin using a small-caliber needle. This provides analgesia and hemostasis. However, most boys will not tolerate this since the injection is distinctly uncomfortable.

More recently, the authors have reported using topical EMLA cream (eutectic mixture of local anesthetics) applied over the entire glans to anesthetize the meatus and perimeatal skin for urethral meatotomy.[6,7] Others have recently reported a similar use for EMLA cream.[8] The EMLA cream is applied liberally over the entire glans, especially on the ventrum. It is secured in place with an occlusive dressing and left in contact with the glans skin for 1–1.5 hours before the procedure (Figure 10.7). The cream is removed and the meatotomy is completed. The vast majority of patients experience no discomfort when EMLA cream

Figure 10.6 Vertical incision for meatotomy following 60 seconds of clamping with a hemostat.

Figure 10.7 EMLA cream is applied over entire glans prior to meatotomy. This remains for at least 60 minutes before the procedure.

is used with this technique. Occasionally, there will be a sensation of pressure when the hemostat is clamped. This is almost always at the most proximal point of clamping. In an occasional patient the EMLA cream may be supplemented with a small amount of injected lidocaine with epinephrine, which seems to be minimally uncomfortable when given following EMLA. Uncommonly, a patient may require a suture on each side of the meatotomy for oozing from the meatal edges following the procedure.

Patient tolerance of the procedure overall is quite good as long as a caring and patient approach is taken to reassure boys before and during the procedure. The room is quiet with minimal lighting and parents bring some of the child's books and hand-held toys for the waiting period after the EMLA is applied. Parents stay in the room during the procedure and this further reassures the child. The authors have chosen, based on parental preference and patient personality, to use midazolam hydrochloride as an anxiolytic with good results in some patients. However, the general observation has been that midazolam is unnecessary for the majority of patients.

Following meatotomy, it is crucial to keep the edges of the meatus separated so that restenosis does not occur. Immediately following meatotomy, while still in the office, the parent is shown how to apply antibiotic ointment within the meatus. The parent then continues this at home, using one hand to separate the meatus while the other index finger is used to place a small amount of ointment directly into the meatus. This is continued twice daily for the first 2 weeks and then once daily for another 4 weeks. Alternatively, a small tube of ophthalmic ointment (Lacri-Lube) may be used as a meatal dilator. A small amount of the ointment is extruded from the metal tip for lubrication and the tip is then passed within the meatus. It is of appropriate size to serve as a dilator for most boys undergoing meatotomy. The use of meatal dilation may be helpful in certain cases if readherence of meatal edges is problematic, but the authors do not feel that it is routinely required.

Patients may be expected to experience mild dysuria for the first 1–2 days postoperatively. It has generally been helpful to have them take ibuprofen or acetaminophen 2 hours preoperatively to decrease discomfort. Boys at the age of 3 or 4 years may respond to meatotomy by holding the urine for prolonged periods of time. Placing them in a warm tub often stimulates voiding in this circumstance. One value of keeping ointment over the meatal edges is that it functions as a barrier to shield the surface from the passage of urine and the resulting discomfort. It should also be noted that increasing the fluid intake for the first day or two following the procedure dilutes the urine and leads to less dysuria. Minor blood spotting in the underwear following meatotomy is common for 1–2 days. Printed handouts are given to parents with these recommendations and they are warned of the risk for restenosis when the instructions are not followed. In addition, boys who remain wet following meatotomy, from either still being in a diaper or having problems with persistent incontinence, are at risk for redeveloping stenosis based upon recurrent inflammation of the meatus. This group may not be candidates for treatment until dryness is achieved. Two out of 226 patients seen by the authors required a second meatotomy. Over the same period that they have used EMLA cream for analgesia, the authors have chosen to perform meatotomy in the operating room in three boys due to patient behavioral issues, including extreme attention deficient disorder. As experience has been gained, it has become apparent that midazolam works well in the moderately overactive, anxious, or difficult young boy, and meatotomy in the operating room should be reserved for the patient with BXO or posthypospadias meatal stenosis.

Non-neonatal circumcision

The pros and cons of newborn circumcision have been and will continue to be debated. Less discussion surrounds circumcision after the newborn period, when it is estimated that 1 in 100 uncircumcised boys will require circumcision.[9] During childhood the most common indication for circumcision is phimosis. This develops because of preputial irritation leading to inflammation, scarring, and thickening of the preputial opening so that the foreskin cannot retract. Hygiene then becomes a problem and, occasionally, this process is so severe that urine flow is affected and the preputial sac dilates with urine dribbling out after voiding. In some patients with chronic skin irritation and inflammation, fissures of the prepuce develop. This makes spontaneous erections and retraction of the foreskin painful, and discomfort occasionally awakens the patient during sleep. Steroid ointments may reduce inflammation, but circumcision is indicated if fissures persist.

Balanoposthitis is an infection of the glans and preputial sac. This infection occurs uncommonly, but can be painful. Skin flora are usually the predominant organisms found on culture. If the balanoposthitis is mild, sitz baths and topical antibiotic ointment (bacitracin) may be sufficient. If cellulitis and fever are present, then a systemic antibiotic is added. The first episode of balanoposthitis is not a mandatory indication for circumcision. Recurrent episodes strengthen the argument for circumcision. Penile hygiene should be reviewed with the parents and patient.

UTIs are more common in uncircumcised boys, especially during the first 6 months of life. Some consider a UTI in a boy an indication for circumcision. After 1 year of age the increased risk for UTI in the uncircumcised male diminishes.

Penile cancer is known to be prevented by newborn circumcision. It is thought that the development of penile cancer closely correlates with penile hygiene, and in developed countries where hygiene is good, the rate of penile cancer is very low regardless of circumcision status. Since penile cancer is very uncommon, the likelihood of a serious circumcision complication may be higher than the eventual possibility of penile cancer.

Occasionally, trauma to the prepuce leads to circumcision. Zipper trauma is the most common occurrence. Usually, with local anesthesia, the zipper can be dislodged by simple advancement or at times by cutting the median bar of the zipper, thereby allowing the teeth to separate. Occasionally, circumcision may be warranted acutely.

After the newborn period the indications for circumcision are relatively few. Circumcision is generally performed under general anesthesia after the newborn period, although a recent report documents the use of local blocks and circumcision in boys beyond this period.[10] Depending upon the age of the patient and the size of the penis, surgical excision and suturing or newborn clamps may be used. The procedure is usually successful, with low complication rates, and is performed on an outpatient basis. Recovery is generally prompt, with the older patients experiencing more discomfort and having a longer recovery period.

Genital holding

Children who hold or clutch their genitalia are often of concern to their parents. This behavior begins shortly after toilet training and may last through the prepubertal years. It is more common in boys than girls. In boys, some degree of genital holding is almost universal. This behavior is thought to have no significant sexual or psychological implications;[1] is thought to be normal and does not warrant any diagnostic studies. Seldom is there any underlying physical cause and evaluation beyond physical examination and urinalysis is not warranted. The best advice for parents is to have them redirect the child's attention without placing great emphasis on this behavior. Generally, over time, children learn more acceptable public behavior without the apparent preoccupation for genital holding. Occasionally, very persistent holders may be told that the behavior may make others uncomfortable, and that for this reason, if they must hold themselves, they should do this in private. Parental education and reassurance is the best course of management.

Female-specific problems

Urethral prolapse

The circumferential eversion of urethral mucosa through the urethral meatus may be seen in girls and is termed urethral prolapse. It is associated with vascular congestion and possible strangulation of the prolapsed tissue. It is possible to have a partial or incomplete prolapse, but complete urethral prolapse is more common.[11] The etiology of urethral prolapse is unclear. Suggested causes include: poor attachment between the inner longitudinal and outer circular and oblique smooth muscle layers of the urethra associated with antecedent episodes of increased abdominal pressure, mucosal redundancy and vaginal mucosal atrophy, estrogen deficiency leading to lax periurethral fascia, neuromuscular disorders, urethral malposition, increased width of the urethra, poor bladder support, and deficient elastic tissues.[12] Predisposing Valsalva maneuvers such as chronic coughing, asthma, and constipation, as well as UTI and trauma, have been reported.[13–16]

Urethral prolapse is often misdiagnosed as the cause of urogenital bleeding in girls. The correct diagnosis at presentation has been reported at only 21%.[17] It is important to recognize that the prolapse appears as a doughnut-shaped mass protruding at the vulva

Figure 10.8 Urethral prolapse: note the doughnut appearance with urethral meatus centrally.

(Figure 10.8). The mucosa is edematous, friable, bright red, or blue-black. As time goes on it may become infected, ulcerated, necrotic, or gangrenous.[11] The differential diagnosis of urethral prolapse includes a prolapsing ectopic ureterocele, prolapsed urethral polyp, ectopic ureter, prolapsed bladder, urethral cyst, hydrometrocolpos, condyloma acuminatum, sarcoma botryoides, and periurethral abscess. The diagnosis of urethral prolapse is visual and based on the typical circumferential appearance of the lesion around the meatus. None of the other stated conditions has a similar appearance. At times, diagnostic confirmation is made by placing a catheter or an instrument tip demonstrating that the urethra is actually in the center of the edematous tissue. Imaging studies are not necessary, but a voiding cystourethrogram (VCUG) can show a narrow, distal urethra.[18] The age range at diagnosis in pediatric series is from 5 days to 11 years, with a mean of 4.5–6 years.[14,16,17,19,20] Urethral prolapse has been reported in identical twins.[21] Also, ≥90% of girls with urethral prolapse are of African descent in most reports.[14,17,22]

In addition to bleeding, symptoms include dysuria or frequency in 25% of girls;[14,16,17,19] 9% of the patients are asymptomatic, with the urethral mucosa showing no tenderness.[11,16] Urogenital bleeding from a urethral prolapse may be mistaken as being from a vaginal source.[14,16,17,19,23]

Treatment options vary for urethral prolapse. Simple treatments should be tried first, including observation alone, topical antibiotic ointment, topical estrogen cream, and sitz baths. Surgical treatments include primary excision, reduction and catheterization, suture ligation of the prolapsed tissue over a catheter, and in adult women cryoablation has been reported.[24] Most published series recommend conservative therapy.[14,17,19,23,25,26] Surgical treatment should be reserved for those rare instances of recurrence or persistent, symptomatic prolapse.[12,14,17,19,23]

Labial adherence

Labial adherence, midline fusion of the labia minora, is a common acquired lesion in young girls. Before puberty the labia minora are covered with a thin hypoestrogenized epithelium.[22,27] An irritating event, such as infection, trauma, or inflammation, causes the area to become denuded and inflamed, and the medial labial surfaces adhere with a fibrinous exudate over their surfaces.[22] Perhaps the most common inciting event is ammoniacal irritation. Adherence generally begins posteriorly and progresses anteriorly, leaving a small opening for the urine just inferior to the glans clitoris[28] (Figure 10.9). Occasionally the process begins near the clitoris, forming a 'preputial fusion'.[22] Labial adherence is also known as labial adhesions, labial agglutination, gynatresia, vulvar fusion, coalescence of the labia minora, vulvar synechiae, labial fusion, and occlusion of the vaginal vestibule. Differential diagnosis includes scarring of the labia minora, imperforate hymen, vaginal agenesis, clitoral hypertrophy, and intersex disorders.[27]

Labial adherence is fairly common and accounts for a large number of the genital abnormalities seen in girls. The peak incidence is between birth and 2 years old and again around the age of 6–7 years, although fusion can be seen until puberty.[28,29] Most girls with fused labia are asymptomatic but some have a deflected urinary stream or vaginal pooling of urine. Dysuria, generally secondary to the underlying inflammatory process, may be a persistent complaint. Patients may present with the diagnosis of UTI;[28] however, the suspected infection may simply be a contaminated specimen, as urine pools beneath the fused labia before exiting. True adhesion of the labia can occur in sexually abused girls with an incidence of approximately 3%.[27,30] This scarring is often thick and irregular in texture, and involves deeper layers.[31]

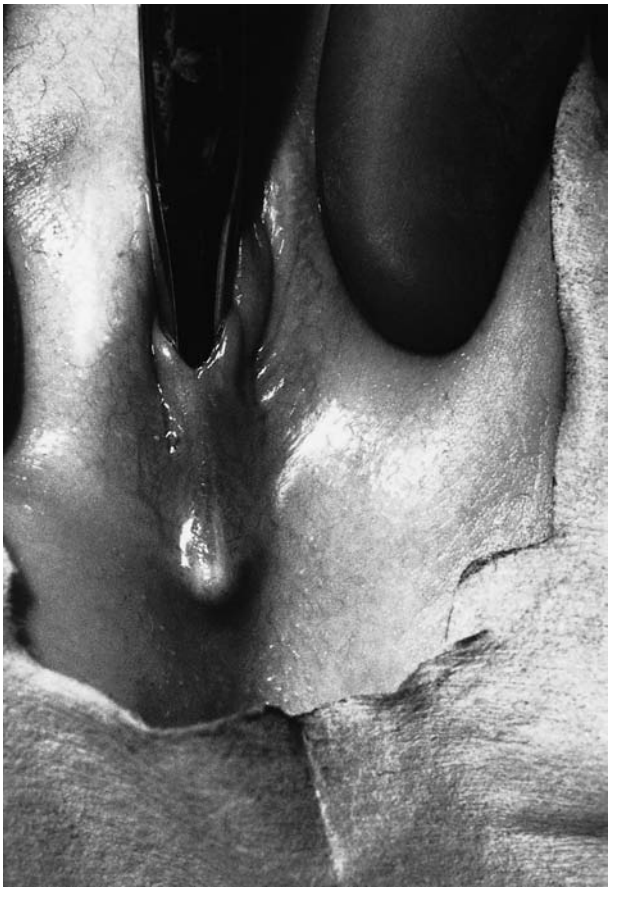

Figure 10.9 Labial adhesions characterized by fusion of the labia minora. There is generally a small opening anteriorly.

Treatment of adherent labia minora is not routinely required. Parents and referring primary care physicians should be reassured that they will lyse spontaneously given time. If treatment is thought to be necessary, estrogen cream can be applied daily, with success reported to be as high as 90% at 8 weeks.[27] The side effects of the estrogen cream will include vulvar pigmentation in all of the patients and breast tenderness in 6%, which resolves after the estrogen therapy is discontinued.[28] However, the long-term effects of estrogen given to prepubertal girls are unknown and treatment beyond a few weeks is probably unwarranted. Persisting adherence can be separated in the office using topical anesthetic (EMLA) and gentle, blunt separation.[22,27,28] An oral anxiolytic may be considered in such girls for this procedure.

Following separation, daily separation of the labia with application of an ointment should be continued for a time to prevent recurrence.[27,28] Forceful separation without analgesia is not recommended.

Vaginal cysts

Incidental vaginal cysts are uncommon and are often found in the newborn period, possibly as a consequence of stimulation by maternal estrogens. They are usually single and between 1 and 3 cm in diameter. When recognized in newborns, evaluation should include passage of a catheter or instrument into the vaginal introitus to assure patency. Rarely, ultrasonography may be necessary to ensure that the vagina is normal and not obstructed. These cysts almost always rupture spontaneously or resolve over a few weeks and need no further treatment. Introital cysts are of several types, including Gartner's duct cyst, Müllerian duct cyst, and epithelial inclusion cyst.

Gartner's duct is the distal rudimentary portion of the wolffian (mesonephric) duct in girls. These ducts in girls usually regress and almost completely disappear. If remnants persist, they are usually found along the anterolateral walls of the vagina. Flat, cuboidal cells line the cyst.[32] Gartner's duct cysts present as a perivaginal mass and usually appear in infants.[33] These cysts can be large enough to protrude from the vaginal introitus or fill the vagina and block its opening.[30,33,34]

Müllerian duct cysts are remnants of non-fused portions of the Müllerian ducts. They are generally asymptomatic and do not usually cause problems until menarche.

Most epithelial inclusion cysts are remnants of the urogenital sinus. Following trauma or surgery, buried vulvar or vaginal epithelium may also cause epithelial inclusion cysts. These are rare in children, although not uncommon in older women.[32] They usually occur posteriorly and in the midline of the vagina.[35] The cysts contain thick caseous material with a squamous epithelium lining their inner surface.[32] Surgical excision is the treatment of choice.[34]

Hydrocolpos

Distention of the vagina with fluid or mucus secretions is called hydrocolpos. If the uterus is involved, the term is hydrometrocolpos. The vagina can be obstructed from an imperforate hymen, transverse vaginal septum, or atretic vaginal introitus.[36] This produces a bulging, shiny, pearly gray protuberance observed over the vaginal introitus.[33,36] The urethral meatus can be noted anterior to the mass (Figure 10.10). Large abdominal masses can be palpable or identified on ultrasonography (U/S). Occasionally, urinary retention can be due to a mass effect. Ultrasonography shows a retrovesical oval cystic mass occasionally causing hydroureteronephrosis.[37] Treatment consists of drainage of the obstructed vagina perineally, but occasionally temporary abdominal vaginostomy may be necessary.

Other interlabial masses

Paraurethral cysts are known to occur along the distal one-third of the urethrovaginal wall.[32] The urethral meatus can be displaced, causing compression and a deflected urinary stream or dysuria. These cysts usually rupture spontaneously.[36,38]

Vaginitis

Vulvovaginitis is the most common cause of vaginal bleeding in the pediatric age group.[39] Vulvitis is vulvar irritation secondary to trauma, topical allergens,

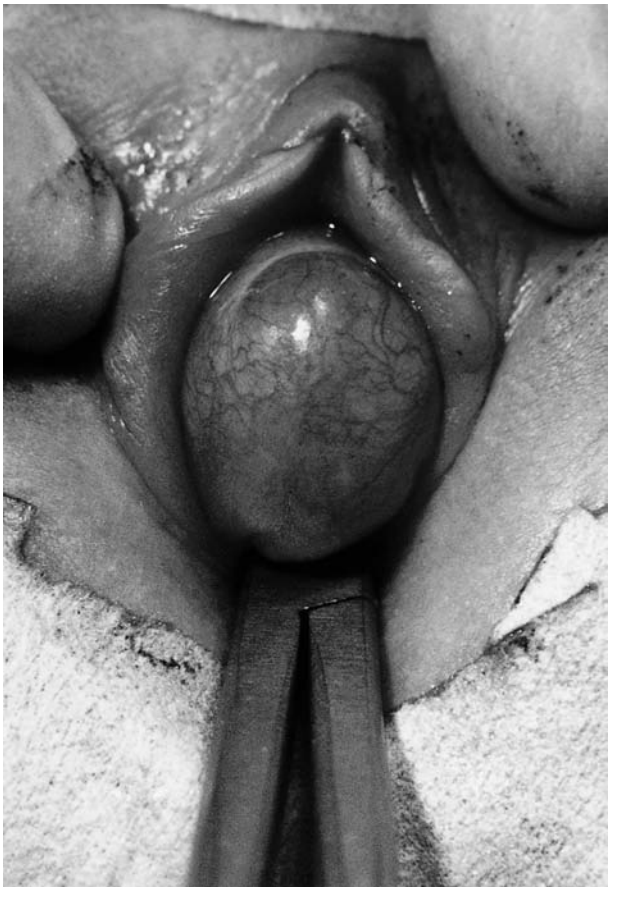

Figure 10.10 Hydrocolpos with duplicated vagina. The urethral meatus is seen splayed above the bulging mass while the hemostat is placed in the patent (second) vaginal opening.

mechanical irritation, chemical irritation, or poor hygiene.[40] Vaginitis is erythema and inflammation of the vaginal mucosa generally associated with discharge. Vulvovaginitis is very often a self-limiting problem and immediate work-up is not necessary. As the symptoms persist or become more annoying, work-up should include sampling of the vaginal pool for pH, wet mount, potassium hydroxide swab, and examination for chlamydia and gonorrhea. A urinalysis with culture may be diagnostic. If specific treatment is desired, a definitive diagnosis must be made.[39] Non-infectious causes in infants and children should be investigated, including ruling out the presence of a foreign body. Foreign body vaginitis symptoms are similar to other types of vaginitis. Toilet paper remnants are the most common objects found in the vagina.

Non-specific vulvovaginitis

Non-specific vulvovaginitis refers to a non-purulent, non-odorous discharge with a neutral pH and normal flora on wet mount. It accounts for 25–75% of all vulvovaginitis seen in premenarchal girls.[38] The etiology includes poor hygiene, urinary soiling, tight clothing, or chemical irritants such as harsh soaps. When testing is normal, treatment consists of reassurance and encouragement of good hygiene and appropriate clothing.

Newborn physiologic leukorrhea

It is normal for newborn girls under maternal estrogen stimulation to have a vaginal discharge. It is usually clear with white–gray mucus not associated with odor or irritation. Wet mount shows numerous epithelial cells without pathogenic bacteria or leukocytes. The discharge diminishes once maternal estrogen stimulation subsides. The tendency towards treatment with vaginal creams and antibiotics should be discouraged.

Genital infections of the young

Sexually transmitted diseases

A common sexually transmitted disease is chlamydial infection caused by *Chlamydia trachomatis*, which is an obligate intracellular Gram-negative organism capable of infecting the atrophic cuboidal epithelium of the prepubertal non-estrogenized vagina.[40] Young children may acquire chlamydia by passing through an infected birth canal or by sexual abuse. In newborns, chlamydia may infect the conjunctiva, pharynx, vagina, or anus. It is estimated that 50–75% of newborns become infected if their mothers were infected with chlamydia.[41]

Gonorrhea is the most common sexually transmitted disease found in abused children and is not likely to occur in children who are not sexually abused.[40,42] It is important to recognize gonorrhea to prevent sequelae and to recognize the child who is sexually abused. Infants can be contaminated through vaginal secretions in the birth canal colonizing the oropharynx, vagina, and rectum. The infection may remain asymptomatic. However, a white, yellow, or greenish, thick vaginal discharge with odor may be present. Labial erythema, urethral irritation, proctitis, or dysuria may be present.

Yeast infections

Other than the cutaneous variety associated with diaper rash, yeast infections are more common in adult females than in prepubertal girls. The alkaline vaginal pH of childhood is hostile to yeast.[40] Most yeast vaginitis is caused by *Candida albicans*. Most often yeast infections are secondary to such predisposing host factors as broad-spectrum antibiotic use or depressed cellular immunity.

Bacterial vaginosis

Less commonly, vaginal infections can be due to bacteria and are often listed as non-specific or *Gardnerella* vaginitis. This is now recognized to be caused by a mixed flora that includes anaerobic bacteria.

Pediatric hematuria

The presence of blood in the urine is a common clinical entity resulting in referral to pediatric urologists. It is a manifestation of abnormalities localized to the urinary tract from the kidneys to the urethra. Hematuria may be visible grossly or seen only on microscopic examination. Urine dipstick measures the presence of hemoglobin in urine and can be falsely positive for hematuria when hemoglobinuria and myoglobinuria are present. Verification of a positive urine dipstick for blood using microscopy can be performed to identify red blood cells (RBCs) within the specimen. To be considered significant for hematuria, urinalysis (UA) requires 5 RBCs per high-power field of a spun urinary specimen. RBC casts, dysmorphic or fragmented RBCs, and RBC blebs on UA signify a glomerular source for hematuria. Gross hematuria accounted for an estimated 1–2 patient visits per 1000 in pediatric emergency clinics.[43,44] The incidence of

microscopic hematuria in asymptomatic children ranged from 14 to 41 per 1000 individuals when a minimum of 4 urine specimens were collected.[45,46]

The evaluation of a child with hematuria should be guided in a systematic fashion as determined by history, physical examination, and laboratory tests. Questions regarding the timing of hematuria relative to gastrointestinal, cutaneous, and respiratory infections are important. The presence of UTI symptoms including dysuria, flank pain, fevers, chills, frequency, and urgency, and a history of recent trauma, prolonged or vigorous exercise add direction to the initial assessment. The character of blood in urine (terminal versus throughout voiding), passage of clots, signs of stone passage including flank pain, nausea, vomiting, and radiating pain associated with hematuria, should be recorded. Documentation of any family history of renal failure, deafness, sickle cell trait or disease, and recurrent hematuria should clue the clinician to a hereditary source of hematuria. Medications, such as non-steroidal anti-inflammatory drugs (NSAIDs), and certain chemotherapeutic drugs, can be causative in the development of hematuria.

Physical examination should identify the presence or absence of flank or abdominal tenderness, extremity edema, pharyngitis, cutaneous rashes, deafness, fever, and hypertension. Urinalyses demonstrating proteinuria and/or abnormalities of RBC morphology are present in diseases involving the glomerulus or its basement membrane. Nitrites, leukocyte esterase, white blood cells (WBCs), and bacteria should prompt urine culture to tailor antibiotic treatment. Further laboratory and radiographic testing should be based upon clinical suspicion.

Asymptomatic microscopic hematuria is often identified when routine screening urine dipsticks are obtained in children. The absence of an inciting event (i.e. trauma), proteinuria, infection, hypertension, lower extremity edema, and renal insufficiency is reassuring and most of these patients can be observed with follow-up UA in 3–6 month-intervals until they normalize. When attributable to vigorous exercise or medications (i.e. NSAIDs), repeat UA can be performed every 1–2 weeks after discontinuation of the offending source to confirm resolution of the hematuria. Diagnostic tests such as radiographic examinations (U/S or VCUG) or invasive procedures, including renal biopsy or cystoscopy, are not warranted in these patients.[47] If asymptomatic gross hematuria or persistent microscopic hematuria occurs, diagnostics testing can be tailored, based upon history and physical examination.

When persistent microscopic hematuria develops without a contributory history or physical examination, obtaining calcium/creatinine (Ca/Cr) ratio, parental urinalysis, and hemoglobin electrophoresis (if the patient is of African–American descent), is helpful in assessing for hypercalciuria, benign familial hematuria, and sickle cell disease/trait, respectively. The spot calcium/creatinine ratio is considered abnormal when >0.21 in children >6 years of age.[48] Alternatively, a 24-hour urine collection demonstrating a urine calcium level >4 mg/kg/day is diagnostic for hypercalciuria.[49] In a small retrospective study of children referred for microscopic hematuria,[47] evaluation of serum electrolytes, creatinine, cystoscopy, VCUGs and U/S of the kidneys and bladder failed to show abnormalities. However, serum creatinine and renal U/S are often utilized to assist in the initial evaluation despite their apparent low yield. When normal, parents can be reassured that their child's prognosis is excellent. Nonetheless, these patients should be followed yearly to assess for the development of proteinuria, hypertension, new symptoms, or resolution of hematuria that would alter current management.

When microscopic hematuria is associated with symptoms, patient evaluation should be tailored based on clinical presentation. The concomitant presence of proteinuria, hypertension, and peripheral edema should prompt an assessment to distinguish between glomerular etiologies of hematuria. Laboratory tests including chemistry panel, complete blood count (CBC), C3, C4, albumin, antistreptolysin-O (ASO) and anti-DNAase-B antibodies will facilitate discriminating between the different immune and basement membrane abnormalities. Prompt referral to a pediatric nephrologist should occur in the presence of an acutely ill child, rapidly progressing or chronic glomerulonephritis, patients exhibiting symptoms of nephritic syndrome, uncertainty of a correct diagnosis, or the need of assistance in management and therapy.[50] However, when microscopic hematuria is associated with a small amount of proteinuria, a conservative course with close follow-up can be instituted with further investigation utilizing the above algorithm if evidence of persistence or clinical progression occurs.

If a history of recent trauma is present, computed tomography (CT) and retrograde urethrography are warranted based upon the clinical scenario and judgment. When signs or symptoms worrisome for a UTI occur, protocols should include obtaining urine cultures, instituting antibiotic therapy based on culture sensitivities, and repeating a formal UA and culture

after the infection has been treated to assess for resolution of the hematuria. Non-contrast CT and urine calcium analysis are helpful if urolithiasis is suspected; abdominal imaging (U/S or CT) if an abdominal mass is palpated.

The presence of gross hematuria can be differentiated based upon its appearance. Tea- or cola-colored urine suggests a glomerular source. Bright red urine with normal morphology on microscopic examination suggests a urinary tract etiology for the hematuria.[51] The absence of RBCs on microscopic examination in light of a positive dipstick may be indicative of hemoglobinuria or myoglobinuria. Subsequent work-up for gross hematuria is driven primarily by clinical presentation. Signs and symptoms suggestive of stones, infection, recent trauma, or glomerulonephropathies can follow similar protocols as described for symptomatic microscopic hematuria.

Idiopathic urethrorrhagia is seen in prepubertal boys who present with blood spotting in the underwear between voiding. In a review at our institution, dysuria was reported in ~30% of patients and mean age at presentation was 10.1 years old.[52] Laboratory and radiographic studies – intravenous pyelography (IVP), U/S, and VCUG – are routinely normal, although RBCs can be seen in up to 57% of patients.[52,53] Symptoms can persist, ranging from a few weeks to 3 or 4 years. Etiology is unknown, although anterior and posterior urethritis have been documented.[52,54] Cystoscopy is generally considered unnecessary unless symptoms persist >24 months as urethral stricture may be identified. This process is self-limited and resolves by puberty without treatment.

For a review of the diagnostic algorithms presented for pediatric hematuria, please refer to Figure 10.11.

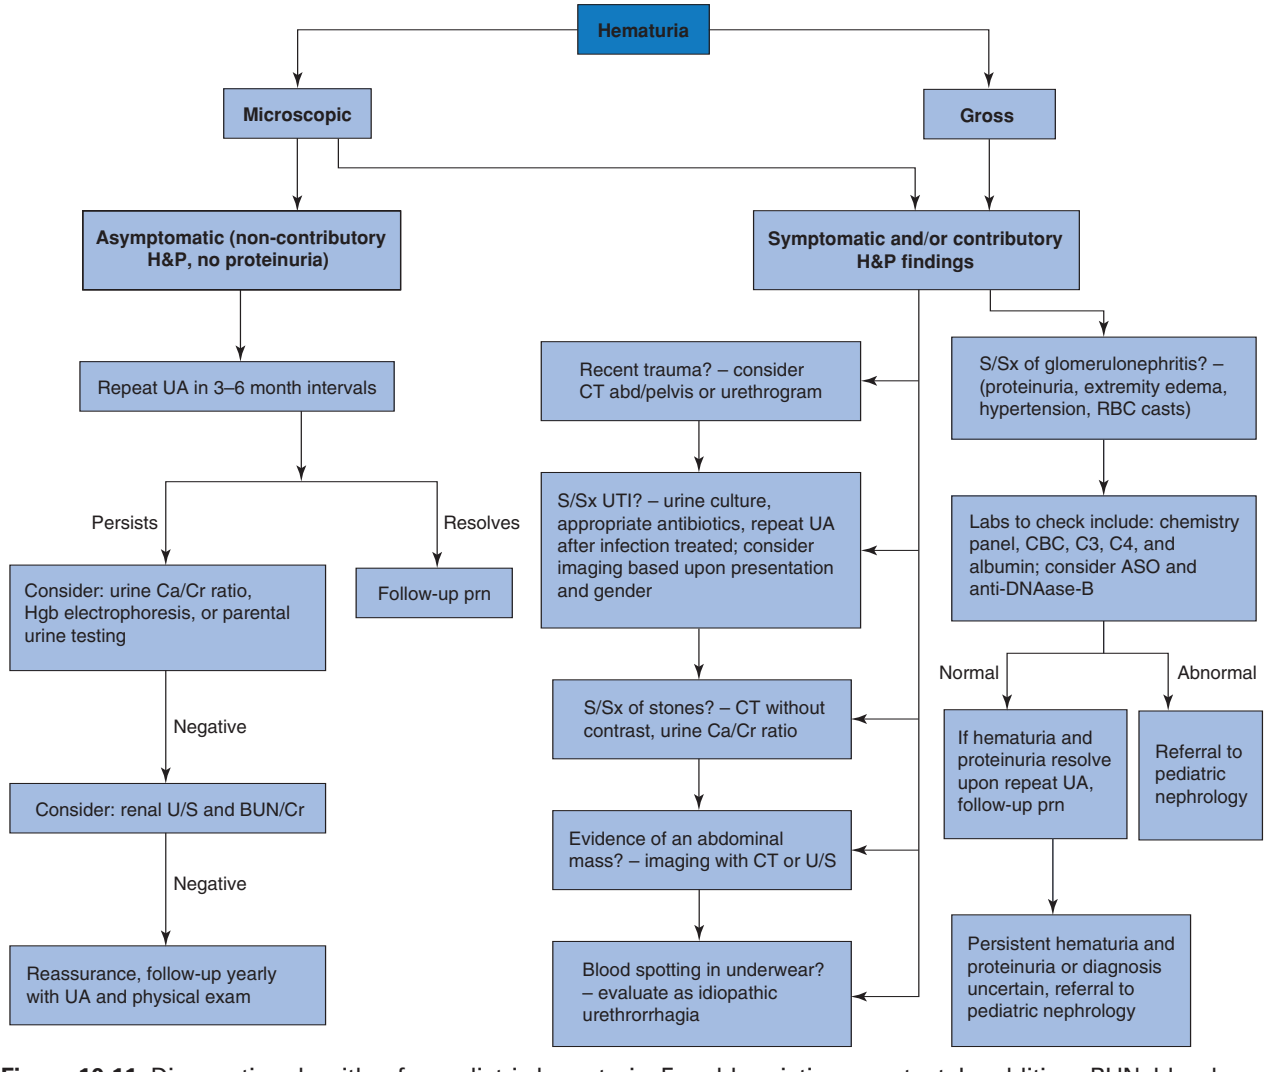

Figure 10.11 Diagnostics algorithm for pediatric hematuria. For abbreviations see text. In addition: BUN, blood urea nitrogen; S/Sx, signs and symptoms; prn, as required; H&P, history and physical examination; Hgb, hemoglobin.

Principles of minimally invasive surgery

11

Walid A Farhat and Pasquale Casale

Introduction

Laparoscopy is becoming increasingly popular in pediatric urology, reducing the invasiveness of treatment and shortening the period of convalescence.[1] With the development of new instruments, better designed for pediatrics, laparoscopy in all ages may be now a safe and effective way to treat many urologic disorders. Nearly any procedure performed in a body cavity can be accomplished using the instrumentation available to us today and the variety of laparoscopic procedures that can be performed in pediatric patients is virtually unlimited.[2] To master this technique, the novice must perform a large number of cases and understand that the learning curve is steep so as not to get discouraged.

Anesthesia

Induction and maintenance of anesthesia may be with either inhalational or intravenous agents or a combination of both. Nitrous gas increases bowel distention, potentially bringing the peritoneum closer to the area of dissection for retroperitoneal procedures and decreasing working space in transperitoneal procedures. Intraoperative monitoring should include a routine electrocardiogram (ECG), non-invasive blood pressure, SpO_2, temperature, and inspired oxygen concentration.[3] Although end-tidal CO_2 may not accurately reflect arterial CO_2 tension, its use is helpful in planning appropriate ventilation strategies. In infants and children with respiratory illness, capillary or arterial blood gas analysis might be needed to accurately monitor CO_2 tension. Maintenance intravenous fluid is usually sufficient unless there is unanticipated bleeding. Finally, it is preferable to insert the intravenous line in the arm on the side of the surgery for a patient in the flank position for easy access.

Anesthesia and physiology

Patient positioning during laparoscopic surgery may potentiate the impact of gas insufflation. For instance, the Trendelenburg position during laparoscopy will increase heart rate and vascular resistance while decreasing mean arterial pressure and cardiac output, whereas the opposite effect is seen in the reverse Trendelenburg position.[4] Furthermore, flank positioning, especially with the kidney rest up and patient flexed, will accentuate impaired venous return and increase cardiac strain. In fact, the left lateral decibitus position produces more significant hemodynamic and respiratory changes than the right flank position.

Pressure effects

As gas is placed in a closed space, it moves depending on the partial pressure gradients. Once the pressure rises, a plethora of cardiovascular, pulmonary, and renal effects may be seen. The heart rate and mean arterial pressure increase while the venous return and cardiac output decrease. These parameters are seen even when pressure is set at a standard working level of 10–15 mmHg. Above this level more profound hemodynamic alterations are anticipated to occur, with further decrease in cardiac output. Furthermore, limitation of diaphragmatic mobility may cause respiratory restriction, manifested by increased airway pressure, requiring an increase in the peak end-inspiratory pressure to maintain a set tidal volume. Finally, renal effects occur secondary to gas insufflation, manifested by decreased glomerular filtration rate (GFR) and urine output. Animal studies have shown that gas insufflation causes renal vein compression, inducing decreased renal blood flow, decreased urine output, and diminished creatinine clearance.[5,6] These effects do not appear to cause renal damage in humans, however.

Absorption effects

Insufflated CO_2 is absorbed into the blood by diffusion, which is limited and determined by many variables; most important are the pressure differential and the cross-sectional area of the absorbing surface. The effects of gas absorption are either pulmonary or hemodynamic. The pulmonary effects are increased CO_2 retention and increased end-tidal CO_2, exacerbated by decreased functional residual capacity and decreased diaphragmatic excursion. The hemodynamic effects of hypercarbia are increased heart rate, vasodilation, and increased cardiac contractility. Although in healthy children there is little if any added cardiorespiratory risk from laparoscopic procedures, children with cardiopulmonary compromise require close and careful monitoring.[3]

Instrumentation

Rapid progress in video technology and the miniaturization of instruments to <2 mm in diameter have made the performance of a variety of pediatric laparoscopic procedures possible.[4] Instruments of this size and larger come in nearly every variety (scissors, needle holders, dissectors, graspers, clamps, suction devices, energy delivery devices, etc.) and facilitate the performance of the most complex cases. The surgical procedure, in combination with the size of the patient, will determine the surgeon's selection of instruments and telescope size. Laparoscopic trocars are available in 3 mm, 5 mm, and 10–12 mm sizes, with corresponding instruments and reducers. Telescopes are available in 3.3 mm, 5 mm, and 10 mm sizes, with varying degrees for optimal visualization. For most ablative or reconstructive urologic procedures, 3 mm or 5 mm trocars are sufficient. However, sometimes 10–12 mm trocars may be necessary if a stapling device needs to be utilized, or when specimen extraction is anticipated.

Access

For all laparoscopic procedures, whether transperitoneal or retroperitoneal, there are two techniques to gain access into the peritoneum: blind access and access through visualization. The blind closed approach is facilitated through the use of a Veress insufflation needle. A stab wound is made with either a #15 or a #11 blade, the Veress needle is inserted through the 1 mm opening, passed through all layers of tissue, and verification of placement is confirmed by opening the stopcock and infusing a small amount of saline into the channel to verify placement typically in the retroperitoneal approach. For transperitoneal procedures, it is more accurate to attach the insufflation needle to the insufflator and monitor pressures. Low pressures (<10 mmHg) are a reliable indication of being intraperitoneal. The second technique is the open (Hasson) approach and is facilitated through the use of direct and telescopic visualization of all tissue during insertion of the trocar with a blunt obturator to gain access into the working space. This technique is generally preferred in children and is especially ideal for obese patients. All proposed trocar sites are injected with bupivacaine 0.5%, with 1:100 000 epinephrine after insufflation and prior to accessory trocar placement.[3] Placement of accessory ports should be carried out using direct vision from within. The location of the accessory trocars depends on the operation to be performed, and specifics of all trocar placements are described below in the transperitoneal and retroperitoneal laparoscopy subsections of this chapter.

Trocar fixation

For all laparoscopic procedures a short (~1 cm) section of rubber, plastic tubing, or cone can be placed around the trocar shaft, about one-third the way from the tip to the hub of the trocar. This prevents the trocar from being pushed into the surgical cavity as instruments are advanced. Prior to CO_2 insufflation, a 2-0 Vicryl (UR-6 needle) suture may be placed around the trocar and in the fascia as a purse-string suture. Once the depth of the trocar is well delineated, this suture is tied to the side of the port and serves several purposes: it prevents the trocar from moving in or out during instrument manipulation; it decreases the possibility of subcutaneous emphysema or leakage of CO_2 from around the trocar site; and it can be used to lift the abdominal wall to enlarge the retroperitoneal space.

Insufflation

Newer insufflators can deliver a great volume of gas rapidly; this may be dangerous in an infant weighing less than 2 kg. In addition to pressure fluctuation, CO_2 insufflation with unwarmed high-flow gas may cool a tiny infant quickly.[3–5] Whereas the rule is to insufflate with just enough pressure to have unobstructed visualization, pressures of 15 mmHg appear

to be well tolerated in any size patient with the only issue being ventilatory compromise in infants with marginal lung function. For all laparoscopic procedures, CO_2 insufflation should be started at a pressure of 12–15 mmHg for children >2 years old and 8–10 mmHg for children <2 years old.

Both the peritoneal and retroperitoneal spaces are closed yet expansible. The physiologic consequences of CO_2 insufflation may be related to the compressive effects of the gas or the metabolic consequences of the gas absorption. With insufflation, the gas will attempt to reach equilibrium with the surrounding environment; such equilibrium is monitored with the use of insufflators that not only control the flow of gas but also monitor the feedback pressure generated from the insufflation.

Operative approaches

Indications for retroperitoneal or transperitoneal laparoscopy

- Total nephrectomy.
- Partial nephrectomy for duplicated renal system.
- Distal ureterectomy for duplication anomaly.
- Pyeloplasty.
- Pyelolithotomy and ureterolithotomy. Extracorporeal lithotripsy and endourologic procedures have almost eliminated the need for open surgery to remove urinary stones. On the other hand, in patients who have unusual anatomy such as ectopic kidneys, a laparoscopic approach may be used either to perform pyelolithotomy or to help in getting direct percutaneous access to the kidney.
- Adrenalectomy for cortical adenoma associated with congenital adrenal hyperplasia.

Contraindications to laparoscopy

Contraindications to laparoscopy in infants, children, and adolescents are the same as for any other surgical procedure, except for evidence of limited lung reserve function, which may be considered as a relative contraindication. If the patient is septic, in shock, or exhibits a coagulopathy, these should be corrected before surgery is contemplated. If surgery is deemed essential under these circumstances, then it probably should be performed open.[4]

Strong contraindications

- Cardiopulmonary morbidity.
- Uncorrected coagulopathy.
- Sepsis.
- Malignant tumors. Although laparoscopy may play a role in the staging of malignant pediatric abdominal tumors such as Wilms' tumor or neuroblastoma, its role in the management of these tumors has yet to be defined. Morcellation of specimens for extraction has raised concerns about accurate pathologic staging; hence, large-sized tumors mandate an incision to retrieve them. In addition, the fragile consistency of the tumor makes it more prone to rupture, and hence may obviate the use of this technique.[5]

Retroperitoneal laparoscopic approach

Relative contraindications

- Prior retroperitoneal scar (kidney surgery, kidney biopsy, or pyeloplasty).
- Previous infectious or inflammatory retroperitoneal process (xanthogranulomatous pyelonephritis), except for experienced surgeons in this approach.

Advantages

- The technique mimics the open urologic surgical procedure through the retroperitoneal approach.
- This direct approach to the organs of the genitourinary tract requires less dissection to the colon or the spleen to expose the kidneys and adrenals.
- Previous transperitoneal surgery does not preclude retroperitoneoscopy.
- Trocar sites have less postoperative hernias than an open incision.
- It facilitates the view of the posterior surface of the kidney hence rapid access to the renal hilum.

Disadvantages

- Manipulation of instruments may be initially difficult due to a restricted working space: e.g. in reconstructive surgery such as a pyeloplasty, suturing and knot tying may be difficult, as well as in ablative surgery, the degree of technical difficulty increases in the presence of large-sized specimens.
- Achieving anatomic orientation may initially be a challenge for the inexperienced laparoscopist.[6]

Anatomic considerations for retroperitoneal laparoscopy

An understanding of the retroperitoneal surgical anatomy is mandatory before embarking on retroperi-

toneoscopic surgery. The boundaries of the retroperitoneal space are:

- posteriorly and laterally – the paraspinous, psoas, and quadratus lumborum muscles, which are anatomically fixed structures
- anteriorly – the mobile posterior parietal peritoneum and its contents
- superiorly – the diaphragm
- inferiorly – contiguous with the extraperitoneal portions of the pelvis.

The retroperitoneum contains the great vessels, kidneys, adrenals, and ureters, in addition to the perirenal adipose and aerolar tissues. Since there is no preformed space, pneumoretroperitoneum is only accomplished after breaking up the adipose aerolar tissue in the retroperitoneum.

Patient preparation and positioning

Bowel preparation for retroperitoneoscopic renal surgery may be recommended in adults; however, this has not been our practice in children.

Although a retroperitoneoscopic approach may be accomplished with the patient prone, we prefer the flank position as it increases the anteroposterior dimensions of the retroperitoneal space and displaces the peritoneal reflection anteriorly, decreasing the chance of inadvertently opening it. The patient is positioned in the full 90° flank position as close to the posterior edge of the table as possible. To further increase the retroperitoneal space, the table is flexed and the kidney rest elevated. Pressure points are meticulously padded and an axillary roll is placed to prevent postoperative complications such as brachial plexus palsy. The patient should be taped to the table using 3-inch adhesive tape placed across the shoulder and the hips so that the patient will remain secured while the table is moved during the surgery.

We prefer to have the surgeon and assistant standing on the same side of the table and we use only one monitor. We believe that having both surgeon and assistant in the same line of vision facilitates eye–hand coordination, particularly that of the assistant surgeon.

Laparoscopic technique

Access to the retroperitoneum is preferably achieved by the open (Hasson) technique, which provides visual guidance. As children have a small retroperitoneal space, and close proximity between the abdominal wall and the major vessels, the closed technique is not recommended. In addition, since there is no actual pre-existing retroperitoneal space, the placement of a Veress needle is not precise and may cause either injury to the great vessels or pneumoperitoneum.

In the midaxillary line, a 1 cm long incision is made 1–2 cm below the tip of the 12th rib. The muscles are split in the direction of their fibers and then the lumbodorsal fascia is incised to enter the retroperitoneum. The method for the development of the retroperitoneal space using a blunt instrument or the balloon dissector is up to the surgeon. Although commercial balloon dissectors are readily available, an inexpensive balloon can be made using the finger of a surgeon's glove tied around a catheter. The balloon is inserted anterior to the psoas muscle and outside Gerota's fascia, and approximately 400–500 ml of air is used to inflate the balloon, creating the space. Instead of using a balloon we introduce a wet gauze close to the posterior muscular wall to create the retroperitoneal space.

Insertion of the primary trocar in the correct space is of paramount importance because inserting the trocar too far medially may result in peritoneal entry or colon injury, whereas entering posteriorly in the quadratus or psoas muscles may cause bleeding. If Gerota's fascia is easily visible, it is incised and opened for direct CO_2 insufflation, although this technique may be associated with inadvertent peritoneotomy. For this reason, it is preferable to create the retroperitoneal space outside Gerota's fascia, dissect the peritoneum medially, and then insert the posterior secondary 5 mm trocar, open Gerota's fascia under vision, and proceed with the creation of the retroperitoneal space by medially dissecting the peritoneal reflection for the third trocar insertion.

We exclusively create the retroperitoneal space using blunt dissection. Through the incision and with the psoas muscle as a reference point, a 10 mm trocar with the laparoscope (0°) is inserted to confirm correct placement. Initially, the posterior–inferior aspect of Gerota's fascia and the lower pole are visualized. Identification of the psoas muscle posteriorly is crucial; on the other hand anteriorly, the edge of the peritoneum is identified and swept medially to expose the underside of the transversalis fascia. To avoid tearing the peritoneum, it is dissected medially by manipulating the laparoscope in a lateral to medial fashion close to the abdominal wall to expose the internal surface of the transversalis muscle. Having created the working space, two 5 mm secondary trocars are inserted. The posterior secondary port is first inserted

approximately midway between the 12th rib and the iliac bone, and lateral to the border of the paraspinous muscles. Using a grasper through this trocar, the peritoneum is further mobilized medially to create the pelvic extraperitoneal space. The anterior secondary trocar is inserted at the anterior axillary line 2 cm superior to the iliac crest. The two secondary ports should be inserted as far apart as possible to improve ergonomics.

In order to place the secondary trocars under vision, a 30° laparoscope may be used. However, we use the 0° telescope, and we insert the trocars in the following fashion for both the retroperitoneal and the transperitoneal approach. A small skin stab is made using a #11 blade; then, using sharp-tipped obturators, the trocars are advanced through the muscles and fascia. Once in the retroperitoneal space, a blunt-tipped obturator is exchanged for a sharp one and the trocars are advanced into the retroperitoneum. This safety tip prevents injury to the peritoneum or the major vessels. In addition, while inserting the trocar, it should be directed toward the area of dissection because if the trocar is advanced away from the site of dissection, this might result in constant tension on the skin during surgery or a greater chance of gas leakage at the trocar site.

Although the sites of the telescope and other trocars are the same for all retroperitoneal renal and adrenal laparoscopic procedures, the sequence of operative strategy and the need for accessory trocars depend on the surgical procedure. In event that more than three ports are required, laparoscopic guidance and bimanual palpation are recommended for accurate placement. For instance, during retroperitoneoscopic pyeloplasty, an additional port may be required to maintain traction on the ureteropelvic junction for better exposure; in this case, a fourth trocar (3 or 5 mm) is placed along the anterior axillary line at the tip of the 11th rib. In order to avoid inadvertent peritoneotomy, adequate dissection of the peritoneal reflection medially at the trocar insertion point is mandatory.

The following laparoscopic landmarks are useful for orientation in any retroperitoneoscopic renal procedure: the psoas muscle and posterior aspect of the kidney are identified first. This approach allows rapid visualization of the 'vertically' oriented main artery and vein. To further facilitate exposure of the renal pedicle, save dissection of the anterior surface of the kidney to the last step. This will maintain retraction on the renal pedicle in case a nephrectomy or a partial nephrectomy is contemplated. In addition, this approach will suspend the kidney anteriorly, exposing the ureteropelvic junction in case a pyeloplasty is performed.

For identifying the renal hilum, locate the psoas muscle, then find the great vessels medially and these will lead to the renal pedicle. In addition, identifying the distal ureter and following it proximally, with the pulsations of the renal artery, aorta, or vena cava, may help to locate the renal hilum. On the right side, initial identification of the inferior vena cava on the medial aspect of the psoas muscle facilitates identification of the gonadal, renal, and possibly the suprarenal veins, which are all located in the same plane. On the left side, the pulsations of the aorta are often visualized and help guide the surgeon to the renal artery.

Transperitoneal laparoscopic approach

Transperitoneal procedures provide exceptional exposure since the intraperitoneal space is large.

Patient preparation and positioning

For upper transperitoneal procedures, positioning the patient in a flank or modified flank position at the edge of the table is crucial. This positioning allows the surgeon to full access of the abdominal cavity without limitations caused by the edge of the table. For the modified flank, a roll should be placed under the torso to provide a 60° patient angulation from the table. The patient should be secured, so that the table may be repositioned as necessary during the procedure. The main monitor should be placed on the lesion side of the operative table, with a slave monitor behind the surgeon. All cables, lines, and wires for the instruments should preferably go off the opposite side to the surgeon. This positioning and port placement is used for the majority of renal interventions such as nephrectomy, heminephrectomy, pyeloplasty, and other renal extirpative and reconstructive procedures. The transabdominal approach also allows access to the pelvis by altering the port use via placing the camera through the subcostal port and instruments through the umbilical and lateral ports.

For lower transperitoneal procedures in infants, it is most convenient to position the patient at the foot of the bed, across the bottom, and to stand at the side of the bed (at the patient's head) to operate.[4] This is a good approach to the bladder. For older patients a mid-table, supine position with a sacral roll to thrust the pelvis up is preferable. Usually the side opposite the lesion is chosen, and the telescope placed centrally in or near the umbilicus. The instrument trocars are

placed lateral to the rectus muscle after insufflation, sufficiently superior and inferior to the telescope cannula so that the instruments can be introduced at a 45° angle relative to the operative field. The monitor should be located towards the foot end of the operative table. Only one monitor is necessary in this scenario. All cables, lines, and wires should be off the foot of the bed for optimal ergonomics.

This approach is extremely helpful for gynecologic and urologic procedures in the pelvis, including transvesical approaches. The new transvesical procedures such as ureteral reimplantation require cannula fixation so that the bladder mucosa does not strip and dissect away from the detrusor muscle. One way to achieve this is to perform a cystostomy at the skin incision to help hold the bladder wall and mucosa to the anterior abdominal wall. A balloon-tipped cannula may also be helpful here, but the size of the balloon tip may impair instrument manipulation in a small child.

Laparoscopic technique

Transabdominal access is best achieved through the umbilicus using the open technique previously discussed, whereby the umbilical scar is lifted using an Allis clamp; then, using a #11 blade, the skin and subcutaneous tissue is incised and peritoneum is entered.

Instruments can be placed directly through a stab wound without the need for a trocar if the surgeon does not anticipate repeatedly withdrawing and reinserting instruments through this site.[6–9]

In infants and thin children, the laxity of the abdominal wall might allow large trocars or heavy instruments to compress the abdominal wall, obscuring vision and limiting CO_2 distention. Once access is attained, sometimes bowel, bladder, or other structures can obstruct the view. It can be helpful to pass one or more sutures through the abdominal wall, through the structure, and back out through the abdominal wall for retraction. These can be tied to a self-retaining retractor or can simply be tied at the distended abdominal wall if that is sufficient.[4]

Technical laparoscopic tips

Suturing

Intracorporeal suturing requires two needle holders or a needle holder and a grasping device. Several sutures can be placed with one length of suture material. A 6 or 7 cm length of suture with its curved needle may be directly passed through 5 mm trocars, but not through 3.5 mm trocars unless the curved needle is first straightened. The suture may also be passed through the abdominal wall to avoid the need for a 5 mm trocar if ≤3 mm trocars are being utilized.

Laparoscopic extracorporeal-assisted tying is possible, but requires a large cannula at one of the port sites. There are a variety of automatic suturing devices and suture assistants; however, it is important for the endoscopic surgeon to become proficient with non-assisted suturing techniques. This is because suture assist devices require larger trocars and are more costly than non-assisted intracorporeal suturing. Furthermore, the majority of devices have a limited choice of suture material and size, and most are not acceptable for complex delicate reconstruction.[10]

An innovative technique for intracorporeal suturing is to tie together the ends of two 5 cm segments of 6-0 Vicryl, one dyed and one undyed, both on a small taper needle, prior to insertion into the peritoneal cavity. The knot tied initially secures the first suture into the renal pelvis and both decreases trauma to the tissue and expedites the anastomosis. The color differentiation facilitates suturing and decreases any confusion and need for repetitive suturing.

Hemostasis

Vessels may be ligated with laparoscopic clip-applying devices that are available in 5 and 10 mm. Laparoscopic tie assisting devices are also available if clips are not preferable. They typically require a ≥5 mm cannula and either have an cinch knot technology or allow extracorporeal tying and knot placement with a pusher device. Freehand laparoscopic tying can also be performed, but is time consuming and does not seem to be beneficial with the current hemostatic devices available.

Laparoscopic stapling devices are available for hemostasis. They are an excellent alternative for large vessels and for transecting thick tissue such as bowel mesentery. The laparoscopic stapling devices require a ≥10 mm trocar for access and come in different lengths, deployment widths, and angulation capabilities. The tissue or vessel is transected as the staples are deployed. One must ensure the device completely traverses the target before deployment, otherwise hemorrhage can occur, especially with large vessels or thick vascular tissue. Stapling devices have been routinely utilized for main organ vessels as well as mesentery with reproducible success. If dividing vascular structures, one must be certain that the device con-

tains vascular and not gastrointestinal staples.

Care should be taken when dividing tissue or establishing hemostasis with high-energy devices, as injury to adjacent structures is possible. A 3–5 mm right-angled hook cautery is a useful device for dividing tissue and preventing hemorrhage. It is important to make contact with the tissue prior to activation of the monopolar electrocautery in order to avoid arcing of current, which may cause a delayed thermal injury to internal structures. Another form of electrocautery that is available is the 3 mm bipolar cautery forceps, which allows for greater control of the current than with standard monopolar cautery.

Tissue extraction

The benign nature of most pediatric renal diseases allows specimen removal with little concern for spillage. In transperitoneal laparoscopic approaches, most structures can be extracted from the umbilical trocar site, whereas in retroperitoneal approaches the site for the specimen extraction depends on its size. This includes segments of bowel, cysts, adrenal gland, biopsies, and nearly anything else compressible. In an infant, these tissues are brought directly through the trocar wound since there are few bags small enough to be of much use. In older children, if a 10 mm trocar is utilized, then endoscopic retrieval bags may be utilized. Larger structures such as intact solid kidneys or heminephroureterectomy specimens may require enlarging a trocar incision to facilitate removal. The umbilical trocar site is typically utilized or a small Pfannenstiel incision can be performed if it is convenient and remains inconspicuous.

Closure

The same technique is used for all laparoscopic procedures. For wounds <3 mm, application of a tissue adhesive or adhesive paper strips is sufficient. Closing the fascia for all wounds >3 mm in diameter is recommended. Fascial closure devices facilitate closure, especially in the obese patient.

Possible pitfalls and solutions

Malfunction of the equipment

Well-trained nurses capable of quickly recognizing and correcting equipment malfunction are mandatory. Since the success of the laparoscopic procedures depends heavily on the proper functioning of the equipment, these cases are best performed when skilled staff are available.

Fogging of the lens

Initially warming the laparoscope in warm saline/povidone-iodine solution or using commercial defogging fluid may avoid fogging of the lens. Inadequate vision, on the other hand, may result from a gas leak around the primary trocar. This usually leads to complete collapse of the retroperitoneal space, and an extra purse-string suture around the trocar may help to decrease the leak. Another possible reason for inadequate vision during retroperitoneoscopy is a peritoneal tear causing intraperitoneal insufflation. It is then necessary either to convert to a transperitoneal laparoscopic approach or attempt venting the peritoneum using the technique described below. Whether a patient has undergone retroperitoneal surgery before or not, dissection of a previously inflamed retroperitoneum may be suboptimal and frustrating and also dangerous; hence, conversion to open surgery may be considered at any time and should not be considered a failure. Families must be aware of this possibility.

Bleeding

Bleeding may occur while bluntly dissecting, especially the retroperitoneal space: in this case, posterior secondary trocars should be placed and the small vessels must be handled carefully using electrosurgical scissors or the bipolar cautery forceps to secure hemostasis.

Subcutaneous emphysema

Subcutaneous emphysema may occur due to leakage of CO_2 into the skin around the area of the ports, as that area is larger than the size of the trocar. Signs of this problem include readily palpable crepitus over the flank and abdomen. Treatment for this complication includes either placement of a purse-string suture around the leaking port, changing the trocar to a larger size, or reduction of the insufflation pressure.

Intraperitoneal CO_2 insufflation during retroperitoneal laparoscopic surgery

If this insufflation occurs prior to the insertion of the two 5 mm accessory trocars, consider transperitoneal or open conversion.

If this insufflation occurs while inserting the secondary trocars (mainly the medial one, superior to the iliac spine), then consider insertion of a Veress needle or an angiocath at the level of the umbilicus intraperitoneally to deflate the peritoneum and change the site

of secondary trocar insertion. Since there is intraperitoneal CO_2 insufflation, the risk of injury to the bowels with the Veress needle or angiocath is minimal.

Potential complications and solutions

Laparoscopic surgery always carries the risk of inadvertent injuries, more common during the learning curve, and increasing experience may lead to a decrease in the complication rates. Since most of the injuries occur during blind access maneuvers with a Veress needle or trocars, the open technique is recommended.

Complications

Great vessel injury may occur from laparoscopic access or dissection. In children the distance between the abdominal wall and the great vessels may be as little as 5 cm. To avoid vascular injury secondary to access, it is advisable to tailor the length of the trocars to the patient age and body habitus.

The hallmark features of vascular injuries include either bloody return from the injury site or rapid deterioration of the hemodynamic status of the patient. Once extensive vascular injury is suspected, the trocar should be left in place and an open exploration should be performed. If minor vascular injury is encountered during dissection, such as laceration to the gonadal vessels or adrenal vessels, hemostasis can potentially be achieved laparoscopically through the use of clips, staples, or ligation.

Bowel injury is a risk of both transperitoneal and retroperitoneal laparoscopy. Because bowel is out of sight during retroperitoneal procedures, injuries may occur during trocar insertion or dissection secondary to lacerations or thermal injuries from electrocautery. If bowel injury is identified during laparoscopy, it is best dealt with at the time of occurrence. If the surgeon is laparoscopically skilled, bowel may be repaired using a laparoscopic approach; otherwise, a general surgery consult is recommended. We believe that a contaminating injury to the small or large bowel is best handled by open repair with or without proximal fecal diversion. In addition, injuries to the liver or spleen may occur while performing laparoscopic retroperitoneal surgery. If the injuries are superficial, attempts to control the injury laparoscopically with gel foam, or with an argon beam coagulator may be undertaken; otherwise, open exploration is recommended. Since these injuries may go unnoticed, inspection of the peritoneal or retroperitoneal space upon access and prior to exiting is of paramount importance.

Finally, port-site herniation may occur in 3 mm and 5 mm trocar sites. Most of the time, it is the omentum that herniates through the port site. This usually requires taking the patient to the operating room for definitive management. A few published reports state that 3 and 5 mm trocar sites should be closed; however, no definitive algorithm exists. It is at the discretion of the surgeon whether closure of these wounds is warranted. Nonetheless, since trocar site closure in the pediatric patient is relatively straightforward, one should consider it in order to prevent the potential complication of herniation.

Pediatric fluid management

12

James M Robertson

Introduction

The human body is composed mostly of water, which accounts for up to 80% of the body weight of a preterm infant and 60% of the weight of an adult.[1] The remaining fraction of weight comprises the structural components: protein, mineral, and fat.[2] Body water, with its dissolved minerals and gases, is what Claude Bernard referred to in 1879 as a 'bit of primeval sea within us all'.[1] The precise maintenance of body fluids and their constitutions are critical to the normal function of the body.

Parenteral fluid therapy was first reported during the cholera epidemic of 1830, in which an alkaline salt solution administered parenterally was credited with saving the life of a moribund young woman.[3] Early in the 20th century, again in response to diarrhea and gastrointestinal (GI) losses, the idea of replacing fluid and electrolytes in amounts that mirrored losses was born. Measurement of the mineral content of infantile diarrhea fluid directed the preparation of oral rehydration fluids.[4] Today, oral replacement therapy is the first-line treatment for dehydration due to GI losses.[5,6]

Perioperative fluid management seeks to maintain fluid and electrolyte balance and adequate circulatory volume in a fasting patient with several types of ongoing fluid and solute loss. In the pediatric population this is complicated by age-related differences in metabolic rate and maintenance fluid requirements, body compartment volumes, and the maturity of homeostatic mechanisms. Inappropriate fluid management can result in significant derangements in electrolyte and fluid balance, particularly in neonates and infants.[7,8]

This chapter provides a brief overview of normal fluid and electrolyte homeostasis, fluid compartments, and maintenance and perioperative fluid management with attention to changes through infancy and childhood. Blood component therapy and alternatives are also discussed. A more detailed account of these topics may be found in one of several texts on pediatric anesthesia.

Fluid and electrolyte requirements

Water requirements

Water is lost through urine, sweat, stool, and insensible losses, including evaporative loss from the respiratory tract. Disease can increase these losses and result in loss to other 'transcellular' compartments such as the GI tract and peritoneal or pleural spaces. Surgery further increases 'third space' losses, defined as fluid sequestered in the interstitium, which no longer contributes to intravascular volume, oxygen delivery, or waste removal.[9]

Metabolism parallels the utilization of water. The production of one calorie of energy requires a net consumption of 1 ml of water.[1] The requirement for water can then be expressed as a function of the metabolic rate.[10] In 1957 Holliday and Seger made this discovery studying 'hospitalized patients', which they assumed reflected a normal metabolic rate between basal levels and that of a healthy active individual. They plotted caloric requirements versus body weight in awake patients and came up with a curve with three roughly linear portions spanning 0–10 kg, 10–20 kg, and 20–70 kg. Infants and children 0–10 kg require 100 cal/kg/day, whereas older patients require an additional 50 cal/kg/day for each kilogram from 11 to 20 kg and an additional 20 cal/kg/day for each kilogram from 21 to 70 kg.[10] This observation, and the correlation between water requirement and calorie expenditure has led to the approximation of maintenance fluid requirements (Tables 12.1 and 12.2).[10]

Requirements in neonates are complicated by immature renal function and variable oral intake in the first few days of life. In-utero high renovascular resistance protects the developing kidney from the effects of pressure and volume overload. At birth, resistance falls, with a rapid increase in renal blood

Table 12.1 Daily maintenance fluid requirements

Patient weight	100 ml/kg/day for 1st 10 kg	+ 50 ml/kg/day per kg between 11 and 20 kg	+ 20 ml/kg/day per kg beyond 20 kg
0–10 kg	100 ml/kg/day up to 1000 ml/day		
11–20 kg	1000 ml/day	+ 50 ml/kg/day up to 500 ml/day or net 1500 ml/day	
>20 kg	1000 ml/day	Net 1500 ml/day	+20 ml/kg/day

Data from Holliday and Seger.[10]
Examples
4 kg infant requires 4 kg × 100 ml/kg/day = 400 ml/day
17 kg toddler requires 10 kg × 100 ml/kg/day + 7 kg × 50 ml/kg/day = 1350 ml/day
25 kg child requires 10 kg × 100 ml/kg/day + 10 kg × 50 ml/kg/day + 5 kg × 20 ml/kg/day = 1600 ml/day

Table 12.2 Hourly maintenance fluid requirements

Patient weight	4 ml/kg/day for 1st 10 kg	+ 2 ml/kg/h per kg between 11 and 20 kg	+ 1 ml/kg/h per kg beyond 20 kg
0–10 kg	4 ml/kg/h up to 40 ml/h		
11–20 kg	40 ml/h	+ 2 ml/kg/h up to 20 ml/h or net 60 ml/h	
>20 kg	40 ml/h	Net 60 ml/h	+20 ml/kg/h

Data from Holliday and Seger.[10]
Examples
4 kg infant requires 4 kg × 4 ml/kg/h = 16 ml/h
17 kg toddler requires 10 kg × 4 ml/kg/h + 7 kg × 2 ml/kg/h = 54 ml/h
25 kg child requires 10 kg × 4 ml/kg/h + 10 kg × 2 ml/kg/h + 5 kg × 1 ml/kg/h = 65 ml/h

flow and glomerular filtration rate. Sodium reabsorption is poor. Intrarenal gradients of NaCl are not yet developed. As a result, urine-concentrating ability is impaired.[11] In premature infants especially, salt and water losses are dynamic in the first few days of life. Initially minimal, urine output increases in the 2nd and 3rd day of life irrespective of intake. By the 4th day, urine output becomes reflective of fluid and solute intake.[11,12] Fluid requirements are significantly, but variably, increased in premature infants. Proper management requires therapy based on repeated measurement of the infant's weight, urine output, and serum sodium.[11]

Electrolyte requirements

In the extracellular fluid, sodium is the predominant cation and chloride and bicarbonate the predominant anions. In the intracellular fluid, potassium is the major cation. The major losses of sodium, potassium, and chloride occur via the kidney; sodium is also lost in sweat, and in the GI tract (particularly during vomiting or diarrhea).[9] Preterm infants, in particular, have high intestinal and renal sodium losses.[13] Potassium is lost primarily in the urine. The requirement for potassium is also related to cell growth and metabolism. Chloride is lost primarily in the urine and gastric secretions.[9]

Sodium and chloride are the major extracellular osmotic agents. Chloride homeostasis occurs largely secondary to sodium homeostasis; therefore, the sodium content of the body largely determines the extracellular volume. Sodium concentration, tightly regulated by renal function, acts osmotically against intracellular osmoles to effect changes in intracellular volume and osmolarity.[2,9]

Potassium, the major intracellular cation, is critical to normal cellular function. Disturbances of potassium balance can have disastrous effects, particularly on cardiovascular function.[11]

Holliday and Seger observed that human milk contained the minimal electrolyte requirements for infants. Combining this with the observed caloric requirements, they concluded that electrolyte requirements for infants were 3.0 mEq/100 cal/day for sodium and 2.0 mEq/100 cal/day for both potassium and chloride.[10,14] This observation has stood the test of time, and is reflected in current recommended requirements of 2–3 mEq/kg/day of sodium and potassium.[15]

Glucose requirements

Glucose requirements, based on metabolic expenditure, are 25 g/100 cal.[16] As discussed below, routine preoperative intravenous fluid therapy does not seek to replace this loss. Glucose in fluids administered intraoperatively is controversial, as hyperglycemia may result.

Fluid compartments

Total body water

Total body water (TBW) is divided between the intracellular fluid (ICF) and extracellular fluid (ECF). The ECF is further subdivided into the intravascular volume and the interstitial volume and transcellular fluid.

TBW is highest in the preterm infant, at 80% body weight. By term, TBW has decreased to 70–75%. This falls abruptly during the immediate postnatal period to 60–65% during the latter part of the 1st year of life. Most of this perinatal change represents a contraction of the extracellular fluid volume, whereas the later gradual change represents an increased cellular mass, including fat[1,11,17] (Figure 12.1).

Extracellular fluid

The plasma and interstitial components of TBW are relatively high in term and premature babies, at 45 and 60%, respectively. In comparison, the adolescent extracellular fluid (ECF) is 27–30% of body mass, 20% of which constitutes the interstitial fluid.[1]

Intravascular volume is as high as 100 ml/kg in premature or critically ill infants. In normal newborns intravascular volume peaks at approximately

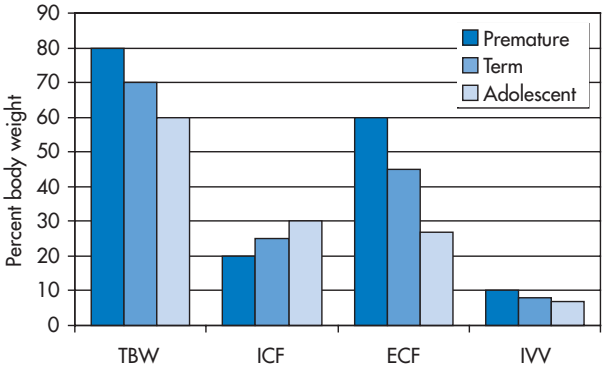

Figure 12.1 Body water distribution. TBW, total body water; ICF, intracellular fluid; ECF, extracellular fluid; IVV, intravascular volume. Data from McManus[11] and Siker.[1]

80–90 ml/kg. It falls to 75–80 ml/kg by 1 year of age. In children 3–6 years old, blood volume is 75–80 ml/kg and >6 years of age it is 65–70 ml/kg, approaching adult levels.[18]

Transcellular fluid is a small division of extracellular fluid separated into anatomic compartments: 1–3% of body weight, it includes cerebrospinal fluid (CSF), pleural and peritoneal fluids, GI fluids, synovial fluid, and the aqueous and vitreous fluid of the eye.[1,19]

Intravenous fluids

Crystalloid

Crystalloid solutions are ubiquitous in medicine. These are simply electrolyte salts dissolved in sterile water, which may be administered intravenously. They are grouped according to their osmolality relative to normal ECF into hypotonic, isotonic, or hypertonic solutions (Table 12.3).

Hypotonic solutions

Hypotonic solutions are solutions with osmolarity less than that of the ECF. Serum and plasma osmolarity in children is 270–290 mOsm/kg.[17] Dextrose in crystalloid solutions is a transient osmole. It is rapidly metabolized, leaving free water behind.[11] Examples of hypotonic fluids include half-normal saline (0.45% sodium chloride) and 5% dextrose in water. 'Two thirds – one third' is commonly heard, and refers to 3.3% dextrose in 0.3% normal saline. It is not particularly hypotonic, with an osmolarity of 269 mmol/L, but once the dextrose is metabolized the remaining solution has an osmolarity of only 103 mmol/L. Free

Table 12.3 Crystalloid solutions

Solution	mmol/L						
	Na	Cl	K	Dextrose	Ca	Lactate	Osmol
D5W				50 g/L			252
D3.3/0.3% sodium chloride	51	51		33 g/L			269
D5/0.2% sodium chloride	34	34		50 g/L			321
D5/0.45% sodium chloride	77	77		50 g/L			406
0.9% sodium chloride (NS)	154	154					308
Lactated Ringer's	130	109	4		1.4	28	272
Lactated Ringer's with 5% dextrose	130	109	4	50 g/L	1.4	28	524
3% sodium chloride	513	513					1027

water dilutes the osmolarity and dissolved constituents of the ECF. The balance between intracellular and extracellular osmolarity is disturbed, and as a result water is drawn into the intracellular space, expanding its volume.

Hypotonic fluids are appropriate for maintenance of TBW and electrolyte balance when given in amounts reflective of normal physiologic requirements, as discussed in later sections. Given in inappropriately high amounts, or in patients with inappropriately high antidiuretic hormone (ADH), hypotonic fluids will result in dilution of electrolytes, hyponatremia in particular, and cellular edema or anasarca.[7,20] Such derangements are potentially life threatening.[8]

Isotonic solutions

Isotonic solutions are solutions with an osmolarity that is comparable to that of the ECF. They are used to expand the ECF volume and the intravascular component of it. Since their osmolarity is the same as that of the ECF, there is ideally no change in the intracellular and extracellular osmolar gradient, and intracellular volumes should not change.

Isotonic fluids are appropriate for rapid expansion or resuscitation of the ECF volume and replacement of ongoing isotonic losses: examples of such losses are GI fluids; third spacing, as a result of trauma or surgery; and, to a certain extent, blood.

Hypertonic solutions

Hypertonic solutions are solutions with an osmolarity greater than that of the ECF. Generally, these are fluids with a high sodium chloride concentration. The administration of these fluids expands the ECF volume and also increases the ECF osmolarity; consequently, free water is drawn from the intracellular into the extracellular spaces. In theory, these solutions can achieve resuscitation with less free water administration and therefore reduce the incidence of edema.[9] This has led to their use in closed head injury patients with elevated intracranial pressure.[21] The other main use of hypertonic solutions is for correction of symptomatic hyponatremia when the benefit of rapid correction is felt to outweigh the potential risk.[21] Otherwise, these solutions are not generally used for maintenance or intraoperative replacement therapy.

Colloid

Normal capillary membrane permeability limits the passage of large molecules such as protein. The effect is that these colloid particles, confined to the vascular space, exert an osmotic pressure. Colloid osmotic pressure, otherwise known as oncotic pressure, serves to maintain intravascular volume.[21]

Colloid intravenous fluids take advantage of oncotic pressure to primarily expand the intravascular space. Examples of colloid solutions are albumin and synthetic dextrose starches and gelatins.

Colloid solutions, including albumin, have a limited half-life in the intravascular space. Capillary leakage of colloids does occur and may exacerbate edema in pathologic states. Colloids, by diluting normal plasma proteins, have been associated with an iatrogenic coagulopathy.[22] Despite these limitations, colloid solutions are a useful adjunct to the resuscitation of intravascular volume in the face of ongoing losses. Five percent albumin is the colloid most commonly used in pediatric patients.[1]

Preoperative fasting

The days of 'nothing after midnight' have past. Excessive fasting times imposed to minimize the risk

of pulmonary aspiration of gastric contents during anesthesia have deleterious effects. Prolonged fasting produces a hungry, irritable, and uncooperative patient.[23] Clear fluids have been shown repeatedly to be rapidly cleared from the stomach.[24,25] This is true even in obese patients.[26] In fact, gastric volume was found to be increased after a prolonged fast when compared with patients allowed 5 ounces of water 2 hours preoperatively.[27] The Canadian Anesthesiologists' Society adheres to the following preoperative fasting guidelines.[28]

The duration of fasting should be:

- 8 hours after a full meal (meat, fried or fatty foods)
- 6 hours after a light meal (toast)
- 6 hours after infant formula or non-human milk
- 4 hours after breast milk
- 2 hours after clear fluids.

These are guidelines, that must be considered critically. The ingestion of a 'filling' meal was found to be associated with gastric emptying times in excess of 9 hours in adults.[29] The American Society of Anesthesiologists adheres to essentially the same guidelines. The fast required after a full meal is not specified: in practice, no full meal is allowed on the day of surgery.[30]

Preoperative fluid therapy

In a patient without abnormal losses, capable of oral intake, adherence to current fasting guidelines will create minimal fluid deficits and electrolyte derangements. This patient needs no preoperative intravenous fluids and the intravenous access may be delayed until the patient arrives in the operating room.[1]

Patients kept NPO (nothing by mouth) for longer periods for medical or surgical reasons must receive parenterally administered fluids and those with abnormal sources of fluid loss need special attention. Maintenance fluids are based on metabolic requirements, as described in the previous sections. Based on metabolic rates, 25 g of glucose is required per 100 calories metabolized.[16] This would require 25 g of dextrose per 100 ml, or 25% dextrose in a crystalloid solution. In practice, when more than 5–10% dextrose is given intravenously at rates adequate to meet water requirements, a glucose diuresis results.[1] The use of 5% dextrose, while providing only 20% of the calories that are expended, results in a decreased starvation-induced protein catabolism and a reduced renal solute load.[1] For most children a solution of 5% dextrose in 0.2% saline with potassium 20 mEq/L added provides adequate replacement of metabolic losses[22] over the short term. This provides 3.4 mEq/100 ml of sodium and 2.0 mEq/100 ml of potassium, which approximates the daily requirements predicted by Holliday and Seger.[10] In patients NPO and unable to receive enteral feeding for prolonged periods, total parenteral nutrition should be instituted.

The rate of maintenance fluid therapy is based on the work of Holliday and Seger discussed above. Since in an awake hospitalized patient the amount of fluid required in milliliters is equal to the energy expenditure in calories, the daily fluid requirements follow the same graded algorithm: 100 ml/kg/day are required for each kg of body weight between 0 and 10 kg, each additional kg between 11 and 20 kg requires an additional 50 ml/kg/day, and each kg beyond that requires 20 ml/kg/day (see Table 12.1). Hourly calculations use the 4–2–1 rule, derived from this daily requirement: 4 ml/kg/h for each kg between 0 and 10 kg, + 2 ml/kg/h for each additional kg between 11 and 20 kg, and 1 ml/kg/h for each kg beyond 20[11] (see Table 12.2).

Intraoperative fluid therapy

In the operating room parenteral fluid therapy deals primarily with ongoing surgical losses such as blood, lymph, third spaced fluids, and insensible losses, which include, in this setting, evaporative losses from the surgical field. These losses are generally isotonic, with the exception of insensible losses, which are solute free. During the stress of surgery ADH is increased, resulting in excess free water retention relative to sodium.[1,7] Relative to awake resting requirements, there is an increased need for sodium replacement intraoperatively.

Isotonic fluids are used intraoperatively at rates necessary to maintain intravascular volume and adequate perfusion. Isotonic fluids equilibrate across the ECF space. The intravascular space makes up one-third to one-quarter of this volume. Replacement of blood loss with crystalloid solutions requires three to four times the estimated volume lost.

The choice of isotonic fluid should be based on the patient's individual requirements. Normal saline, classed as isotonic, is slightly hypertonic, with an osmolarity of 308 mosm/L and a sodium concentration of 154 mEq/L. This may be advantageous for

initial expansion of the ECF and intravascular volumes. Saline, however, contains chloride in excess of normal physiologic concentrations. Excessive saline has been associated with hyperchloremic metabolic acidosis.[31] Balanced salt solutions, such as lactated Ringer's, model extracellular fluids. These fluids are most commonly used for ongoing replacement of intraoperative losses. Normally the lactate is metabolized by gluconeogenesis to glucose and by oxidation to bicarbonate. Both processes consume hydrogen ions and result in a base excess with bicarbonate production.[22,32]

The rate of intraoperative crystalloid therapy takes into account the ongoing losses in addition to the maintenance requirements. Blood may be replaced in a one-to-one ratio with colloid or three- to fourfold with crystalloid. Third space losses occur relative to the degree of trauma incurred. Several estimates of the rate of these losses have been published. Minor surgical procedures, such as inguinal hernia repairs, may involve third space redistributive losses of 3–4 ml/kg/h, whereas moderately traumatic procedures such as cholecystectomy may involve third space losses of 5–7 ml/kg/h. Major abdominal procedures in small infants may result in third space losses of ≥10 ml/kg/h.[33,34]

Albumin is the colloid most often used in pediatrics. There is a paucity of evidence regarding synthetic colloids in pediatrics. Albumin, despite years of use, remains a controversial issue.[1] The appeal of colloids, such as albumin, is their ability to expand the intravascular space rapidly and persistently. However, in conditions with increased capillary leak, albumin will be redistributed to the interstitial fluid and act osmotically to increase interstitial edema at the expense of plasma volume. Furthermore, mobilization of third space fluid postoperatively may be hindered by interstitial colloid.[1] Hetastarch is the synthetic colloid most studied in pediatrics. Hetastarch 6% was found to be as effective as albumin in expanding plasma volume in children after cardiopulmonary bypass. Volumes up to 20 ml/kg of 6% hetastarch were given safely; beyond this, a dilutional coagulopathy was detected, although not clinically relevant.[35]

Intraoperative glucose

The administration of dextrose to pediatric patients under anesthesia has been a subject of debate for decades. The fear is that preoperative fasting and low glycogen stores in infants may predispose them to hypoglycemia intraoperatively.[22] Premature infants are at elevated risk of fasting hypoglycemia due to reduced glycogen stores.[1,11] General anesthesia masks the physical signs and symptoms of hypoglycemia and it would be undetected in the absence of blood glucose determination.[36] The risk of preoperative hypoglycemia due to fasting is estimated at 1–2%.[22] Intraoperative stress increases blood sugar in most patients, with the possible exception of the very young.[1,36] The incidence of intraoperative hypoglycemia is low but a lipid mobilization does occur, with generation of plasma ketone bodies and fatty acids.[36] The use of 5% dextrose solutions intraoperatively has been associated with hyperglycemia. Hyperglycemia should be avoided to prevent glucosuria, polyuria, and dehydration.[22] Studies of balanced salt solution with lower concentrations of glucose have been performed. Lactated Ringer's solution with 0.9 or 1% dextrose added has been shown to prevent hypoglycemia in infants and children.[36] A 2% dextrose solution has been shown to prevent lipolysis without producing hyperglycemia.[37]

Blood component therapy

Blood loss is replaced with crystalloid and/or colloid solutions until the maximal allowable volume of loss has occurred. Thereafter, blood is given to maintain an adequate hematocrit and oxygen delivering capacity. The allowable blood loss (ABL) may be calculated preoperatively knowing the patient's weight, estimated blood volume (EBV), initial hemoglobin (Hbi), and minimal allowable hemoglobin (Hbf).[38] Much work has been done to determine the safe lower limits of hemoglobin concentration. In practice, most anesthesiologists use a lower limit of 70–80 g/L.[22,38] Calculating the allowable blood loss in a 1-year-old, 10 kg infant with an Hbi of 120 g/L:

$$ABL = EBV \times (Hbi - Hbf)/Hbi$$[39]
$$ABL = 10\ kg \times 80\ ml/kg \times (120 - 80)/120$$
$$ABL = 800\ ml \times 40/120$$
$$ABL = 267\ ml$$

In the face of ongoing bleeding beyond the ABL or with a measured hematocrit of less than 20–25%, blood component therapy should begin. A unit of packed red blood cells (PRBCs) has a hematocrit of 55–65%. If your target hematocrit is 25%, then the PRBCs may be diluted to achieve a greater volume of expansion. Dilution with saline is advised for slow infusions, since the calcium in lactated Ringer's may

promote microaggregate formation in the intravenous line. A concentration of 3 ml/kg of undiluted PRBCs can be expected to increase a patient's hematocrit by 3% or hemoglobin by 10 g/l.[22] With massive transfusion, dilution of clotting factors and platelets by PRBCs results in coagulopathy and non-surgical bleeding. Fresh frozen plasma (FFP) is often required after the replacement of 1–2 blood volumes.[38] Platelets, depending on the initial count, may be required after 2–4 blood volumes.[38] Fibrinogen and labile factors are diluted after 3 or more blood volumes and may be replaced with cryoprecipitate.

A host of problems may arise with blood component therapy. In addition to transfusion reactions, bacterial contamination, and the low risk of viral transmission, normal constituents of blood products produce metabolic and electrolyte abnormalities. PRBCs contain high levels of serum potassium, as high as 26 mEq/L, depending on the length of storage. Massive transfusion can lead therefore to transient hyperkalemia.[38] Sodium citrate is added to PRBCs to chelate calcium and prevent clotting. Citrate administered with blood during massive transfusion leads to hypocalcemia.[38] FFP also contains citrate and may contribute to hypocalcemia. Hyperkalemia and hypocalcemia with transfusion are dependent on the rate of transfusion. In adults, transfusion rates of citrated whole blood of 1.5–2 ml/kg/min would be expected to result in clinically significant hypocalcemia. FFP also contains 32 mmol/L of glucose and 172 mEq/L of sodium.[40] Hyperglycemia and hypernatremia may occur with FFP transfusion in large amounts.

Patients expected to have significant blood loss should have frequent intraoperative determinations of hemoglobin and platelet levels, coagulation activity, electrolyte and calcium profiles, and arterial blood gases. Massive transfusion and large volumes of crystalloid resuscitation should be directed by individual patient parameters.

Postoperative fluid therapy

Intravenous fluid therapy in the postoperative period is an extension of intraoperative therapy. Losses of blood and other fluids may be ongoing in the postoperative period. Changes in fluid and electrolyte homeostasis are still under the influence of surgical or traumatic stress.[11] ADH levels, increased intraoperatively, may remain elevated in the postoperative period, resulting in water retention in relative excess to sodium reabsorption, producing hyponatremia.[7,11] Hypotonic fluids in the postoperative period may predispose the patient to free water excess and hyponatremia.[7] Fluid losses should be replaced with isotonic fluids.[11] Blood component therapy may need to be continued to compensate for ongoing blood loss or coagulopathy.

Summary

Fluid therapy in the pediatric patient during the perioperative period can be a complex task. Immaturity of renal and homeostatic mechanisms predisposes preterm infants and neonates to significant fluid and electrolyte disturbances with inappropriate therapy. Crystalloid, colloid, and blood therapy should be utilized with a respectful knowledge of the physiology of the patient and the changes induced by disease and surgical stresses. Re-evaluation based on clinical and laboratory data should occur regularly.

Embryology of the genitourinary tract 13

Steven E Lerman, Irene M McAleer, and George W Kaplan

An understanding of the significant events in the embryology of the genitourinary tract is essential to both the diagnosis of congenital anomalies and the interpretation of pathologic findings that result from disordered embryogenesis. The embryology of the genitourinary tract will be presented differently in this edition of the textbook than in the previous ones. In this edition we will separate the embryology into several small chapters, each relating to sections of the text organized by system. This short chapter will serve as a general introduction to the embryology of the genitourinary tract. Each of the embryology chapters presents data synthesized largely from standard textbooks of embryology,[1–3] but each is amplified with newer concepts as they seem clinically pertinent. The material is arranged chronologically as well as by organ to provide a better understanding of the inter-relationships between structures. A developmental 'timeline' is presented in Figure 13.1 for easy reference. As the authors are not embryologists, some might suggest an element of 'armchair embryology', but, as this material is presented only to aid in clinical understanding, this posture may be excusable.

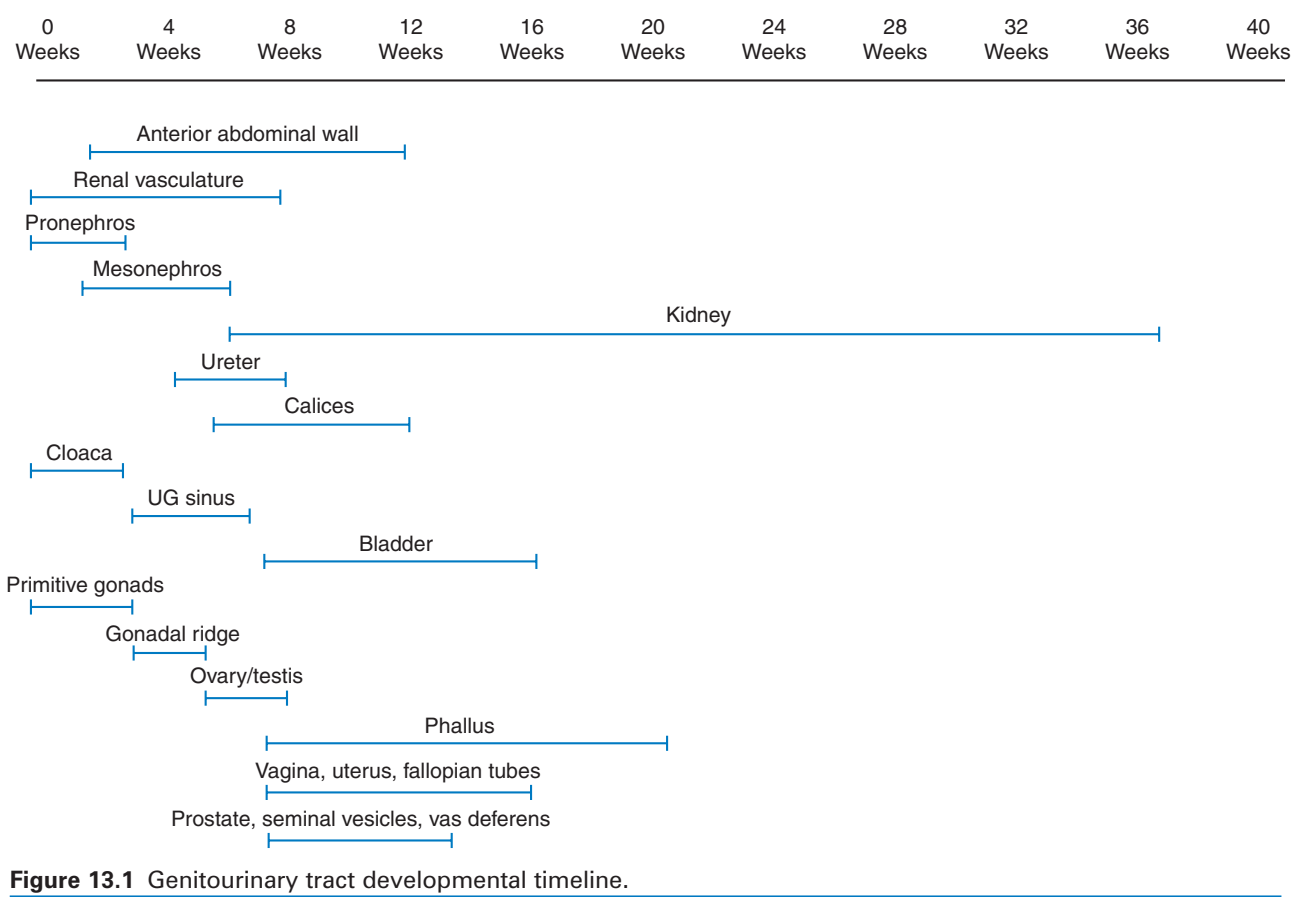

Figure 13.1 Genitourinary tract developmental timeline.

The first events in embryology occur at the time of conception, or fertilization of the ovum by a spermatozoon. It is at this moment, or in the first few subsequent cell divisions, that the chromosomal constitution (karyotype) is established. The normal human cell contains 46 chromosomes (usually written 46,XY or 46,XX), 23 of which are provided by the maternal gamete (ovum) and 23 by the paternal gamete (sperm). The future individual's genotypic sex is now established, as an X chromosome is provided by the ovum and either an X or a Y chromosome by the sperm. It is mostly the presence and expression of the testis-determining factor (TDF) gene, a locus usually carried on the Y chromosome but rarely translocated to one of the other chromosomes, that results in maleness.[1] In the absence of this locus, femaleness is likely to develop. Other non-Y-linked genes involved in sex determination have been found by genetic analysis of XY sex-reversed patients whose phenotype could not be explained by mutations in the TDF gene.[4]

It is presumably at conception, as well, that certain other genitourinary abnormalities related to the individual's karyotypic constitution are determined. For example, many of the intersex states are determined at this time, either as deletions of chromosomes (e.g. Turner's syndrome, 45,XO)[5] or as extra chromosomes (e.g. Klinefelter's syndrome, 47,XXY).[6] The genital abnormalities of the Aarskog–Scott syndrome are also determined at this moment, as they are carried as an X-linked recessive trait.[7] Many of the trisomy syndromes include abnormalities of the genitalia and of the urinary tract as part of their spectra of expression.[8] The syndrome of Wilms' tumor and aniridia is related to a chromosomal abnormality (deletion of the short arm of the 11th chromosome).[9] Many other urinary abnormalities are probably also determined at this time, although the exact nature of many of these processes is as yet unknown. Others that seem to be familial in nature include duplication anomalies,[10,11] vesicoureteral reflux (VUR),[12,13] congenital ureteropelvic junction (UPJ) obstruction,[14] renal agenesis and dysplasia,[15] and hypospadias.[16] Some abnormalities are inherited as autosomal dominant traits (e.g. autosomal dominant (adult) polycystic disease), whereas others (e.g. autosomal recessive (infantile) polycystic disease; adrenogenital syndrome) are autosomal recessive traits.

Early embryonic life can be negatively influenced by teratogens such as heat, viruses, and drugs (Table 13.1). Maternal hyperthermia can induce neural tube defects in the embryo. Hyperthermic states have also been associated with hypothalamic lesions leading to micropenis.[8] Some viruses, when they infect the mother, may produce congenital abnormalities in the fetus. Urologic abnormalities appear more frequently than normal in the congenital rubella syndrome.[17] It is well known that maternal ingestion of drugs can affect the developing fetus. Progestational agents may masculinize a female fetus.[18] The maternal production of androgens by ovarian tumors can also masculinize a female fetus. Maternal use of oral contraceptive pills has been theorized to be associated with the development of hypospadias.[19] The use of angiotensin-converting enzyme (ACE) inhibitors during pregnancy has been associated with renal dysplasia, probably due to the drug's deleterious effects on the developing renal vasculature.[20] The fetal alcohol syndrome, on occasion, includes urinary abnormalities.[21] In addition, the use of anticonvulsant medications during pregnancy has been associated with genitourinary abnormalities in the fetal hydantoin syndrome[22] and the fetal trimethadione syndrome.[23] Maternal use of recreational drugs, such as cocaine and metamphetamine, has been associated with anomalies of the genitourinary system, including Eagle–Barrett syndrome and hypospadias.[24] Excessive vitamin A ingestion during the first trimester of pregnancy has been reported to increase the risk for the development of genitourinary abnormalities.[25] In addition, physical forces (e.g. compression of the fetus within the uterus secondary to oligohydramnios) can induce permanent physical changes in the fetus, even at a relatively late stage of development. These are termed 'deformation syndromes', of which Potter's syndrome is thought to be one.[26]

Table 13.1 Genitourinary (GU) tract teratogens

Teratogen	Potential GU defect
Maternal hyperthermia	Micropenis
Rubella virus (congenital rubella)	Hypospadias, cryptorchidism
Progestational agents	Ambiguous genitalia
Oral contraceptives	Hypospadias
ACE inhibitors	Renal dysplasia
Ethanol (fetal alcohol syndrome)	Hypospadias, hydronephrosis
Anticonvulsants	Hypospadias, ambiguous genitalia, cryptorchidism
Cocaine	Eagle–Barrett syndrome, hypospadias, hydronephrosis

Increasingly, disorders of embryogenesis can be detected on prenatal ultrasound. For this reason, the evaluation of the pediatric urological patients often begins in the fetal stage. Moreover, potential parents are seeking preconception guidance from specialists regarding genetic risks to a potential fetus. These families are interested in ways to detect and/or quantify these risks and to understand ways to minimize them. Answers to many of these questions are forthcoming as results of detailed molecular and genetic studies continue to provide clinical information.

Section II

The Adrenal

Adrenal or suprarenal gland development

14

Steven E Lerman, Irene M McAleer, and George W Kaplan

The adrenal or suprarenal glands are located near the superior poles of the normally placed kidneys and contain two distinct different functioning areas of tissue, the cortex and the medulla. Although anatomically very close, the cortex and the medulla arise from two different and distinct areas. The adrenal medulla is derived from migrating ectodermal neural crest cells. The cortex develops from the primitive mesoderm medial to the urogenital ridge, starting about the 4th gestational week. By the 6th week, the cortex is apparent as an aggregation of mesenchyme on either side of the root of the mesentery and the developing gonad. At this time, nerve fibers, which the developing medullary cells will traverse, penetrate the developing adrenal cortex. The cortex develops two distinct areas by the 8th gestational week. The central area or the fetal zone is laterally and centrally located, while a thin rind develops on the outer aspect of the adrenal as the ultimate definitive adult cortex. The definitive cortex begins to differentiate into hormone-producing zones, the zona glomerulosa and the zona fasciculata, late in gestation. Most of the developing proliferation during the latter part of gestation is in the peripheral cortex region. The zona reticularis does not become apparent until about the end of the 3rd year of life (Figure 14.1). The zona glomerulosa or outermost layer of the definitive cortex will produce aldosterone. The zona fasciculata and zona reticularis will form a unit after the reticularis develops in early childhood. The zona fasciculata will produce the glucocorticoid hormones, while the zonal reticularis will produce the sex or androgen hormones.

Adrenal arterial circulation develops from developing descending aorta; several arteries feed the adrenal cortex and infiltrate from the cortex to the medulla in a fine network of vessels. A central vein drains each adrenal gland.

The adrenal glands increase in size from around the 2nd–3rd month of gestation, growing from about 5 mg to 80 mg. They are much larger than the adjacent kidney for much of development and remain large even after birth (Figure 14.2). Most of this mass

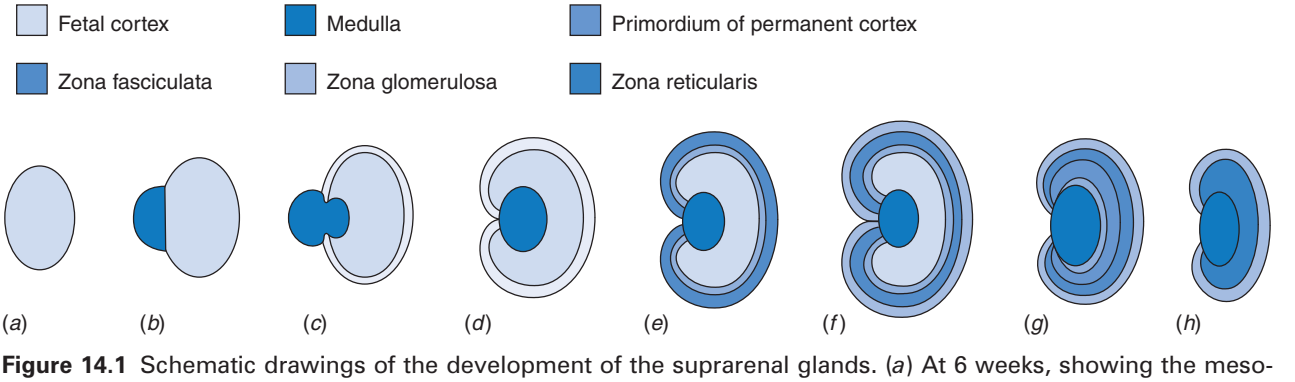

Figure 14.1 Schematic drawings of the development of the suprarenal glands. (*a*) At 6 weeks, showing the mesodermal primordium of the fetal cortex. (*b*) At 7 weeks, showing the addition of neural crest cells. (*c*) At 8 weeks, showing the fetal cortex and the early permanent cortex beginning to encapsulate the medulla. (*d* and *e*) Later stages of encapsulation of the medulla by the cortex. (*f*) Newborn infant, showing the fetal cortex and two zones of the permanent cortex. (*g*) At 1 year, the fetal cortex has almost disappeared. (*h*) At 4 years, showing the adult pattern of cortical zones. Note that the fetal cortex has disappeared and that the gland is smaller than it was at birth (see *f*). (From Moore and Persuad,[1] with permission.)

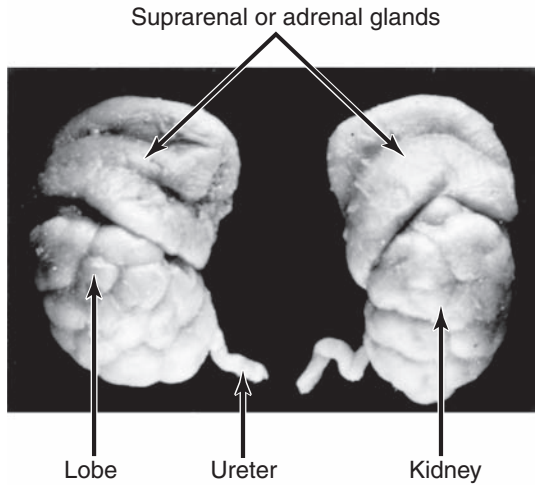

Figure 14.2 Photograph of kidneys and adrenal glands of a 28-week-old fetus. The external evidence of the lobes usually disappears by the end of the 1st postnatal year. Note the large size of the suprarenal glands at this age. During the first 2 weeks after birth, these glands reduce to about half the size. (From Moore and Persaud,[1] with permission.)

is due to the fetal cortex and the developing definitive adult cortex; the adrenal medulla is quite small until after birth. The adrenals lose most of their mass shortly after birth, with about one-third of the weight lost in the first 2–3 weeks after birth. The loss in mass is due to the involution of the large fetal cortex zone. The original weight is not regained until about the end of the 2nd year of life.

Primitive adrenocortical cells may migrate beyond the normal suprarenal location during formation. Accessory adrenocortical rests may be found adjacent to the celiac plexis, in the broad ligament, near the ovarian or spermatic vessels, or around the kidneys or uterus. Rarely, these rests may be found near other abdominal organs or even the lungs, spinal nerves, or in the brain. Some of these rests may be responsible for Cushing's disease or malignant degeneration.[2]

The medulla arises from the neural crest cells of the primitive sympathetic nervous system. The migrating neuroectodermal cells differentiate into neuroblasts, ultimately forming the paravertebral and para-aortic sympathetic ganglia, and the pheochromoblasts, which will form catecholamine-secreting chromaffin cells. The chromaffin cells are found throughout the adrenal medulla and the sympathetic chain in the fetus but the extra-adrenal sites generally involute after birth. Persistent extra-adrenal tissue can be found near the origins of the celiac and mesentery arteries; another site, the organs of Zuckerkandl, is located near the inferior mesenteric artery and may be prominent during the first year of life, after which, this tissue generally involutes but may be a site of extra-adrenal pheochromocytoma development later in life.

The fetal adrenal cortex produces large amounts of dehydroepiandrosterone sulfate (DHEA-S) after the first trimester. It is uncertain when steroidogenesis actually begins, but steroidogenic enzymes (CYP11A and CYP17) are noted at about 50 days postconception in the human fetus.[3] The outer cortex is believed to produce cortisol after about 28 weeks' gestation.

The fetal hypothalamic–pituitary–adrenal axis (HPA) is an example of reciprocal induction where the development, differentiation, and maturation of vital organ systems (lungs, brain, liver) for immediate postnatal survival and parturition are hinged on interactions between the organs of the developing endocrine axis.[1] The hypothalamus releases corticotropin-releasing hormone (CRH) as early as 8–12 weeks' gestation. CRH regulates the secretion of the pituitary corticotropins (adrenocorticotropin is the pituitary corticotrophin hormone ACTH), proopiomelanocortin (POMC) mRNA expression as well as acting as a potent vasodilator of the fetoplacental circulation, and potentiating local prostaglandin and oxytocin function for uterine contractions during labor.[4] Placental estrogens facilitate conversion of fetal cortisol to inactive cortisone which causes a negative feedback on the fetal HPA axis, resulting in increased POMC mRNA, ACTH, adrenal cortisol, and DHEA-S production. Interestingly, increased fetal adrenal glucocorticoid stimulates the release of placental CRH, which increases the stimulation on the fetal pituitary to increase ACTH release. This causes the adrenal to produce more cortisol, which is critical for the transition from fetal life to extrauterine life at the end of gestation. The importance of this up-regulation of cortical hormone for transition to infant well-being and survival after delivery has been shown in outcome studies of extremely preterm small neonates who were delivered prior to attaining the normal adrenal developmental milestones in utero.[4–6]

Molecular extracellular components necessary for adrenal medulla and cortical development and maturation include collagen IV, fibronectin, and laminin.[7,8] These proteins are necessary for normal cell regulated apoptosis as well as smooth migration of the neural crest component of the adrenal medulla.

A serious and potentially life-threatening condition is congenital adrenal hyperplasia (CAH), which is a group of autosomal recessive disorders, the most

common of which is caused by a mutation of the cytochrome P450 21-hydroxylase (*CYP21*) gene. This mutation causes deficient production of cortical enzymes necessary for producing corticosteroids or mineralosteroids needed for life. Other forms of CAH are not as common, and the etiology of the defects are also not as well known. The decreased cortical hormone production stimulates the fetal pituitary to produce more ACTH, which then causes the adrenal to enlarge and produce more adrenal androgens and androgen precursors that do not require 21-hydroxylation. The excess androgen activity will cause masculinization of female fetuses. The excessive hormone production must occur within the first trimester to produce the masculinization changes which can only take place during early genital development.[3,9]

Radiologic assessment of the adrenal

15

Kourosh Afshar, Douglas H Jamieson, and Andrew E MacNeily

Diagnostic imaging is an essential part of the investigation of adrenal disorders. Modalities such as ultrasound, magnetic resonance imaging (MRI), and computed tomography (CT) have replaced older techniques such as intravenous urography and angiography. In this chapter we discuss the imaging characteristics of the more common childhood adrenal abnormalities (Table 15.1).

Table 15.1 Differential diagnosis of antenatally detected adrenal masses

Adrenal hemorrhage
Neuroblastoma
Renal duplication anomaly
Pulmonary sequestration
Enteric duplication

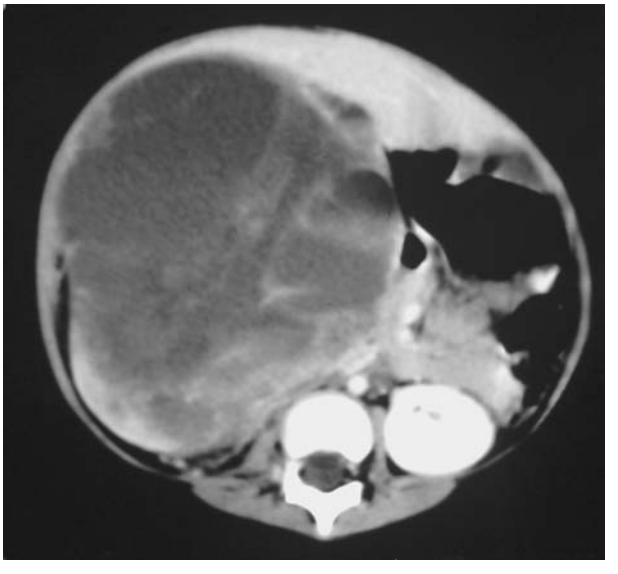

Figure 15.1 Contrast-enhanced CT demonstrates a large heterogeneous mass with areas of non-enhancing low density. It is difficult to separate a mass arising from the upper pole of the right kidney from an adrenal mass. The tumour renal interface is indistinct.

Solid masses of the adrenal

Neuroblastoma

If a solid adrenal mass is encountered when a child is imaged, neuroblastoma must always be considered. These are malignant tumors originating from neural crest cells with a peak age incidence of 2.5 years. They arise from the adrenal medulla in 40% of cases, the remainder being extra-adrenal in origin. Although they can be detected incidentally at the time of imaging for other indications, neuroblastoma usually presents as a large abdominal mass and is metastatic in 70% of cases at the time of presentation.[1]

Calcification, which is amorphous and speckled, is seen on up to 50% of plain abdominal radiographs and 80% of CT scans.[2] On ultrasound, tumors are solid, heterogeneously echogenic with occasional hypoechoeic areas.[3]

Cross-sectional imaging (CT or MRI) depicts a large irregular mass and punctuate calcification with or without enlarged lymph nodes or visceral metastases.[4] Neuroblastoma tends to cross the midline and encase vascular structures. It displaces the kidney laterally and inferiorly (Figures 15.1 and 15.2). These features are helpful to differentiate neuroblastoma from a large Wilms' tumor.[5] On CT, areas of low attenuation often represent areas of cystic necrosis or hemorrhage (Figure 15.3, 15.4a–b).[5] On MRI, the mass has low or intermediate signal intensity on T1- and high intensity on T2-weighted images.[6] CT- or MRI-based myelograms are useful in selected cases to assess the extent of intraspinal extension, which presents as a dumbbell-shaped tumor (Figure 15.5a–b,

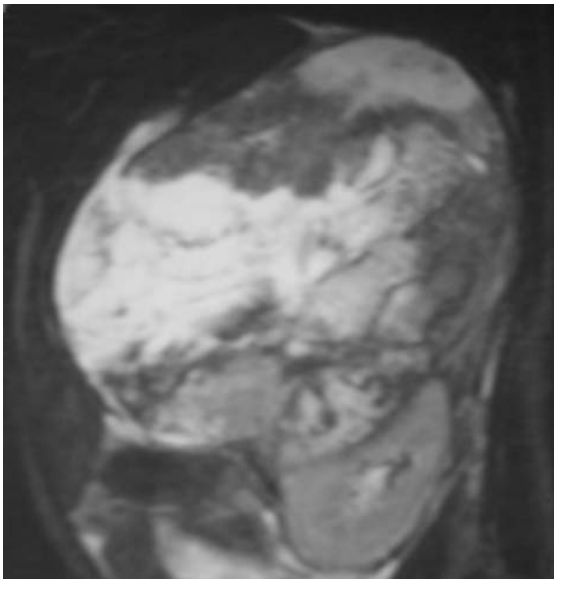

Figure 15.2 Sagittal T2-weighted MRI image clearly demonstrates tumor mass displacing the right kidney inferiorly confirming adrenal mass. The tumor mass has large areas of increased T2 signal intensity corresponding to the low density areas on CT (Fig. 15.1). Areas of tumor necrosis or old areas of hemorrhage are suspected.

Figure 15.3 Contrast-enhanced CT in a 4-year-old child presenting ill, with weight loss and a hard abdominal mass. There is a large mass in the left adrenal/retroperitoneal location. Dense areas of opacity indicate calcification. The mass enhances poorly and inhomogeneously. Lymphadenopathy surrounds the aorta, displacing it away from the vertebral body. Histology confirmed neuroblastoma.

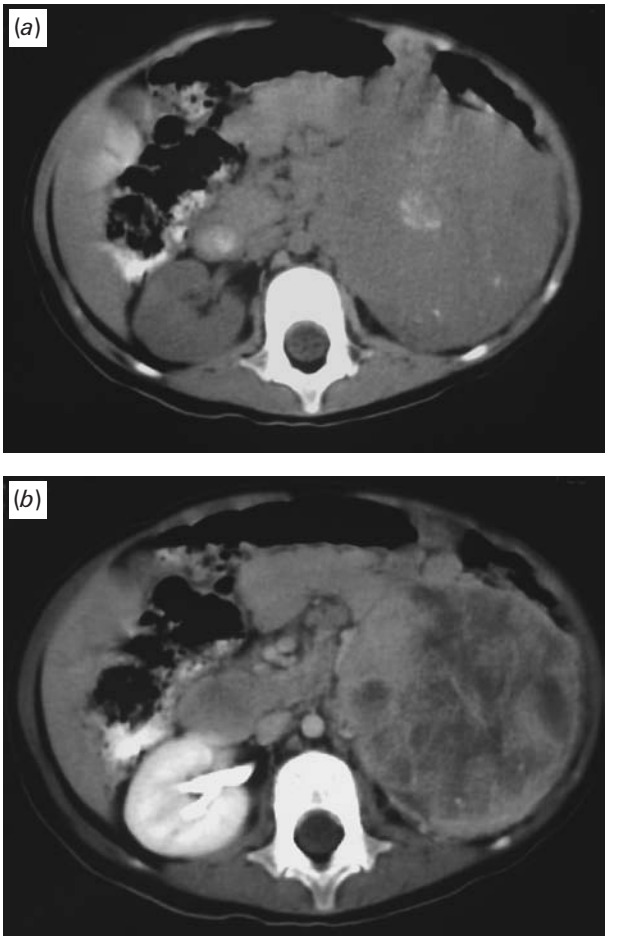

Figure 15.4 (*a*) Non-enhanced CT demonstrates a large left neuroblastoma mass with calcification. Note the nodal spread to right renal hilar region also has calcification. (*b*) Contrast-enhanced CT slightly inferior to *a* shows marked inhomogeneity of enhancement.

and 15.6a–c).[7] Iodine^{132} or I^{131} or I^{123} metaiodobenzylguanidine (MIBG) scintigraphy demonstrates uptake by the primary tumor and any metastatic sites, such as bone.[8,9] However, MIBG has up to 30% false-negative results in diagnosing primary tumors and is less sensitive than 99m technetium methylene diphosphonate (^{99m}Tc MDP) at diagnosing bony metastases. In practice, the two tests are used to compliment each other.[5,10] A recent study concluded that both CT and MRI have poor accuracy for estimating local extension, but when either modality is combined with ^{99m}Tc MDP scintigraphy they are equally useful in diagnosing stage 4, with an accuracy of 90%.[11]

Ganglioneuroma and ganglioneuroblastoma

These benign tumors arise from sympathetic ganglions and represent a more differentiated form of neuroblastoma. On CT they manifest as an oval, discrete mass with variable enhancement. Calcification that is usually not as extensive as in neuroblastoma is seen in 20% of cases. On MRI, the mass has a low-

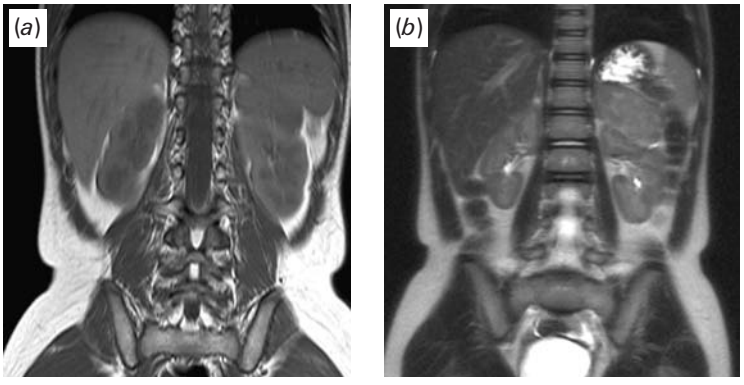

Figure 15.5 Coronal T1 MRI (*a*) and coronal T2 MRI (*b*) demonstrate a left adrenal mass that is homogenous and has soft tissue signal characteristics. This is usual for smaller neuroblastoma where tumor necrosis and hemorrhage are less encountered. Note MRI can easily miss calcification, although this has little impact on diagnosis.

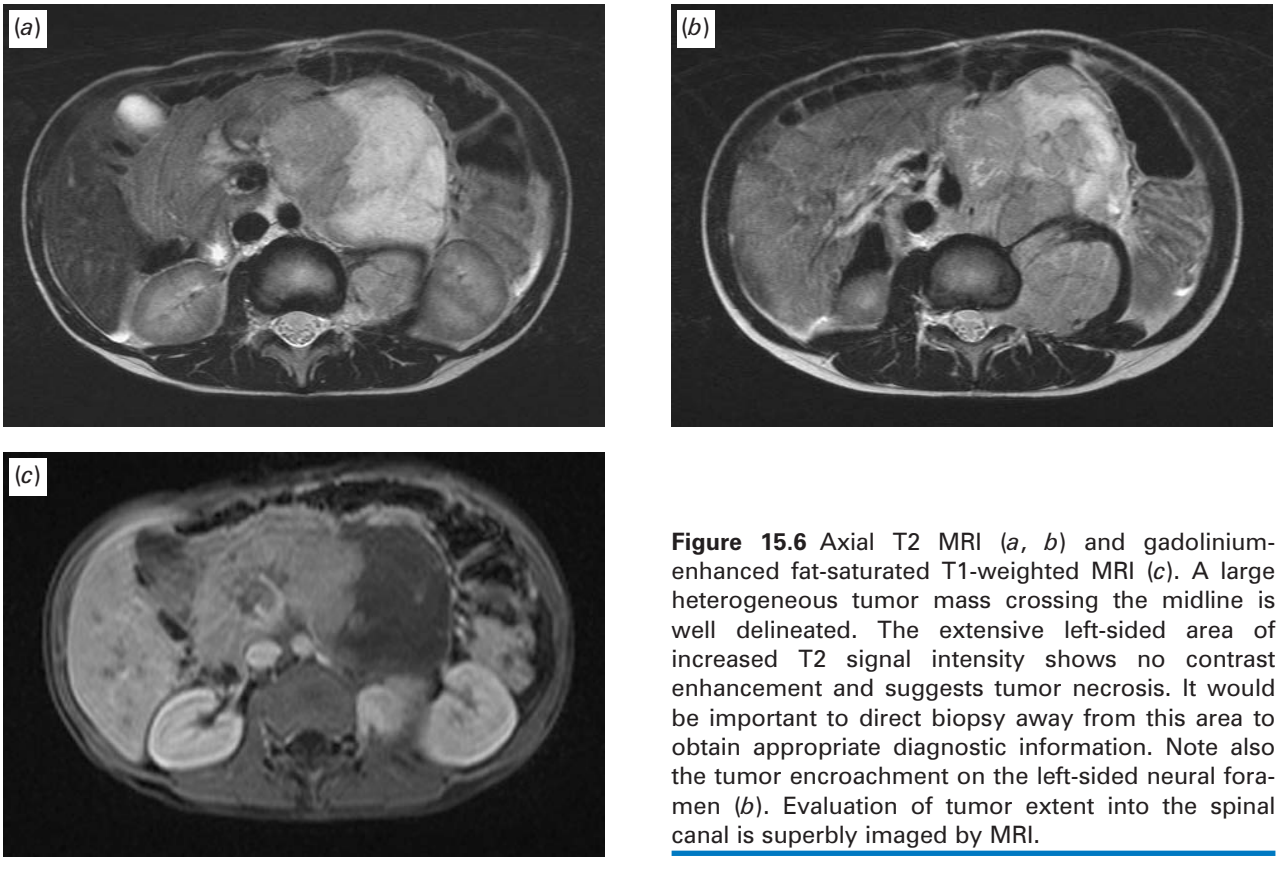

Figure 15.6 Axial T2 MRI (*a*, *b*) and gadolinium-enhanced fat-saturated T1-weighted MRI (*c*). A large heterogeneous tumor mass crossing the midline is well delineated. The extensive left-sided area of increased T2 signal intensity shows no contrast enhancement and suggests tumor necrosis. It would be important to direct biopsy away from this area to obtain appropriate diagnostic information. Note also the tumor encroachment on the left-sided neural foramen (*b*). Evaluation of tumor extent into the spinal canal is superbly imaged by MRI.

intensity signal on T1 and high intensity on T2 images with a characteristic whorled appearance.[12] Ganglioneuroblastoma is an intermediary tumor of sympathetic tissue containing both benign and malignant elements. It has variable imaging features, depending on the composition of the tumor.[12]

Pheochromocytoma

Also a tumor of neural crest cells, pheochromocytoma tends to occur in older children compared to neuroblastoma. The main presentation is headache due to hypertension.[13] On ultrasound, the tumor is seen as a hypoechoic mass, occasionally containing small cysts. Generally, CT and MRI are both highly (>90%) sensitive and specific in diagnosing and staging pheochromocytomas; but because of the possibility of a hypertensive crisis, induced by the iodinated contrast material, some authors prefer MRI as the first choice for cross-sectional imaging. However, at least one study has demonstrated that non-ionic contrast agents are safe in the setting of a confirmed pheochromocytoma.[14] On non-enhanced scans, tumors are isodense to the surrounding soft tissue but enhance

intensely following intravenous (IV) contrast.[15] MRI generally characterizes these tumors as possessing low signal intensity on T1-weighted images and a characteristic marked increased signal intensity on T2 images secondary to their high vascularity.[16] MIBG scans have a sensitivity and specificity of 90% in detecting functioning tumors but without the anatomic resolution provided by cross-sectional imaging.[4,17]

Cortical neoplasms

These are rare tumors of childhood mostly associated with endocrine syndromes.[18] In the absence of metastasis the distinction between adenoma and carcinoma is very difficult, even with histologic study of the removed tumor.

On ultrasound, these tumors present as round or ovoid masses, commonly lobulated. They may be hypo- or hyperechoic and the larger tumors are inhomogeneous.[19,20] On CT, they manifest as circumscribed and heterogeneous masses. The criteria used in adults to differentiate between adenoma and carcinoma, such as non-enhanced densiometry and size, have not been studied adequately in children. On MRI, cortical neoplasms have intermediate-intensity T1 and high-intensity T2 signals.[21]

Myelolipoma

This rare benign tumor is composed of adipose and bone marrow elements. The diagnosis is made based on demonstration of fat on CT or MRI.[22]

Adrenal metastasis

Metastatic lesions presenting as an adrenal mass are rare in children. The imaging criteria to differentiate primary adrenal adenomas from secondary tumors as described in adults, such as attenuation values more than 10 Hounsfield units (HU) or signal loss less than 20% in chemical shift MRI,[23] have not been studied in children.

Renal lesions

Lesions in the upper pole of the kidney should be included in the differential diagnosis of an adrenal mass. Wilms' tumor, renal cell carcinoma, and a

Table 15.2 Imaging characteristics of pediatric adrenal masses

Adrenal mass	Ultrasound	CT scan	MRI	Nuclear scan
Neuroblastoma	Solid mass, heterogeneous echotexture	Heterogeneous, low attenuation areas of hemorrhage or necrosis, calcification up to 80%	Heterogeneous signal on T1 and high signal on T2	MIBG avid in 70% 99 Tc MDP more accurate for bone metastasis
Ganglioneuroma	Solid oval or lobulated mass	Homogeneous attenuation lower than muscle, varying degree of enhancement	Homogeneous low signal on T1 and whorled appearance on T2 with varying degree of enhancement	MIBG may be positive
Pheochromocytoma	Solid tumor, possible cystic area	Intense enhancement with contrast, low attenuation areas of necrosis/hemorrhage	Low intensity T1, extremely high intensity T2 signal	90% MIBG avid
Adrenal cortical neoplasm	Lobulated solid mass	Heterogeneous attenuation	Low T1 and high T2 signal intensity	
Metastasis		Attenuation <10 HU	Signal drop <20% in chemical shift MRI	
Adrenal hemorrhage	Initially hyperechoic with gradual liquefaction	Initial high attenuation (50–60 HU) with no enhancement	Initially: Low signal T1 Intermediate (1–5 weeks): High signal T1 and T2 Late (weeks to months): Low signal T1 and T2	

HU = Hounsfield unit.

hydronephrotic upper pole moiety of a duplicated system can all masquerade as a primary adrenal mass.

Cystic masses of the adrenal

Cystic adrenal masses are rare in childhood. They are usually unilateral and asymptomatic. These lesions may be classified as pseudocysts, endothelial, epithelial, and parasitic cysts. Pseudocysts are formed following hemorrhage into normal or abnormal adrenal tissue. Examples include bleeding into or necrosis of a neuroblastoma or adrenal carcinoma. Calcification is common. Endothelial cysts are the most common category in some series.[24] They may have a vascular or lymphatic origin, and are lined by the corresponding endothelium.[25] Epithelial cysts may be true glandular cysts, embryonal or cystic adenoma.[26] Hydatid cysts constitute the majority of parasitic cysts described in the literature.[27] Typically, cysts are hypoechoic on ultrasound. They possess low intensity on T1-weighted MRI and high intensity on T2. Treatment of adrenal cysts depends on the underlying pathology and ranges from percutaneous aspiration of cysts containing water density fluid, to laparoscopic or open adrenalectomy for more complex lesions.[28]

Antenatally detected adrenal masses

With the advent of routine maternal fetal ultrasound the detection of fetal adrenal masses is becoming increasingly common. Most of these lesions are detected in the third trimester, with the majority being cystic or cystic/solid in nature. Ultrasound is the modality of choice for initial and follow-up evaluation of these findings. In neonates the normally large adrenal glands are clearly visualized and consist of a hypoechoic cortex and a thin echogenic medulla. The differential diagnosis for antenatally detected adrenal masses is shown in Table 15.2. The intensity of imaging and clinical management of these incidental findings must strike a balance between aggressive surgical intervention for a presumed malignancy and watchful waiting for a benign condition, or one which has a natural history of spontaneous involution.

In a retrospective study of 30 prenatally diagnosed adrenal masses reported from Paris, 13 (43%) were ultimately found to be neuroblastoma, the remainder representing mainly adrenal hemorrhage with the rare pulmonary sequestration (Figure 15.7).[29] Antenatally detected neuroblastoma can be either cystic or solid.

Figure 15.7 Contrast-enhanced CT scan confirmed the antenatal and postnatal detection of a left adrenal cystic lesion. Surgical removal confirmed the diagnosis of a pulmonary sequestration.

Of importance is the fact that MIBG scanning only provided a 70% sensitivity and a 55% negative predictive value for neuroblastoma in this population. Similarly, urinary catecholamines provided only 36% sensitivity and 72% negative predictive value. Postnatal features suggestive of neuroblastoma include large size (>3 cm), homogenous solid nature, and growth on serial follow-up. Conversely, development of calcification in follow-up, shrinkage in size, or development of internal echoes suggests a resolving adrenal hemorrhage (Figure 15.8a–b).[30]

Although adrenal hemorrhage classically occurs in the first few days of life in association with neonatal sepsis or other stressors, it may be observed in the second or third trimester of pregnancy and therefore clinical features alone are inadequate to determine a diagnosis.[31] It is the most common neonatal adrenal mass, and occurs on the right side in 70% of cases. This latter characteristic is thought to be secondary to adrenal compression between the liver and kidney anteriorly and the spine posteriorly.[32]

Early ultrasound of an adrenal hemorrhage depicts a hyperechoic mass. Over the initial few days, the hematoma gradually liquefies (Figure 15.9, 15.10). Complete resolution takes up to 6 weeks with occasional calcification or pseudocyst formation.[33] CT and MR scanning are necessary only in selected cases to determine whether blood is the sole component of a mass, a finding that most likely indicates a benign cause. Acutely, CT of an adrenal hemorrhage is manifested as a well or poorly defined mass with increased

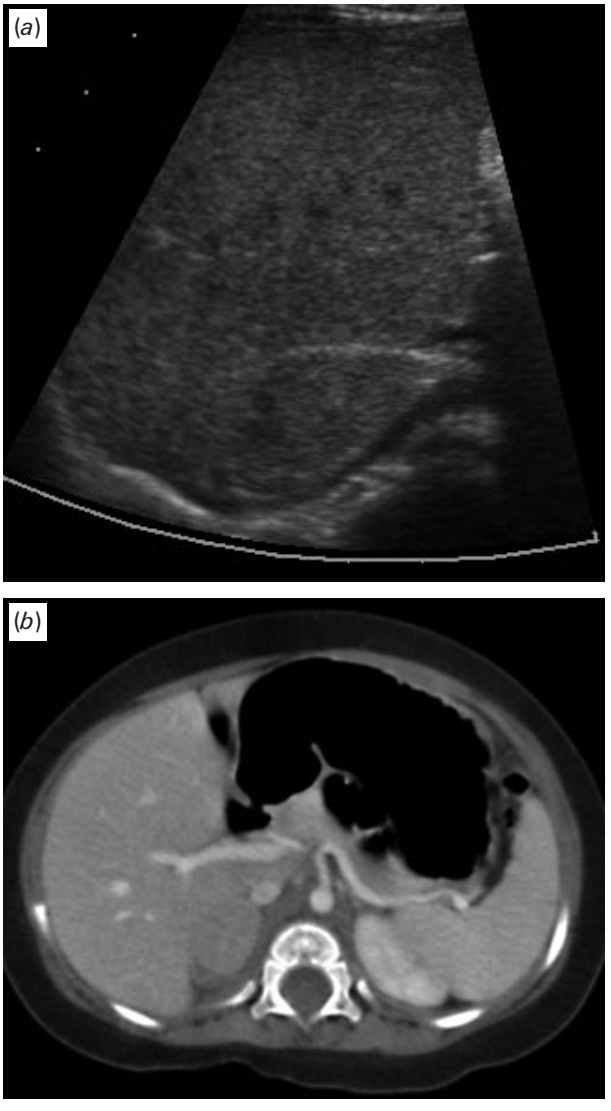

Figure 15.8 (*a*) Neonatal ultrasound performed in follow-up of an antenatally detected right supra-renal mass demonstrates a solid, fairly homogeneous right adrenal mass lesion. Serial images failed to demonstrate involution over the course of several weeks. (*b*) Subsequent contrast-enhanced CT shows a solid homogeneous right adrenal mass, confirmed to be neuroblastoma upon excision.

Figure 15.9 Ultrasound obtained in a 5-day-old neonate following traumatic delivery demonstrates a multiseptated right adrenal mass typical of an organizing hematoma.

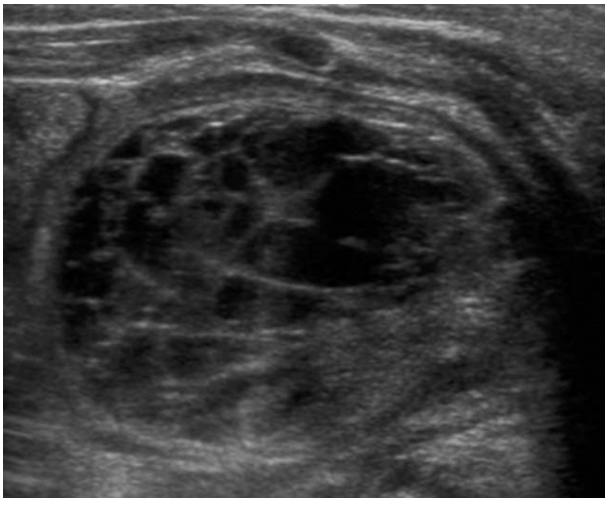

Figure 15.10 Sonogram on day 3 of life, requested to exclude renal anomalies in a patient with transposition of the great vessels. Unexpected but typical findings of a septated left adrenal hematoma. The incident causing the hematoma probably occurred in utero.

attenuation (50–60 HU) that does not enhance with IV contrast (Figure 15.11; Table 15.2). In the acute phase, MRI of hematomas demonstrates a reduced signal on T1-weighted images. Methemoglobin in the subacute phase (1–5 weeks) causes a high signal on both T1- and T2-weighted images. Chronic hemorrhage (5 weeks to 10 months) demonstrates the gradual formation of low-signal hemosiderin.[32,33]

For small antenatally detected lesions, an initial postnatal ultrasound, MIBG scan, and urinary catecholamines should be routine. If initial investigations are suggestive of a benign process, then monthly ultrasounds for the first 6 months suffice. Surgical removal is recommended for an increase in size, elevated urinary catecholamines, or failure of involution with observation.[34]

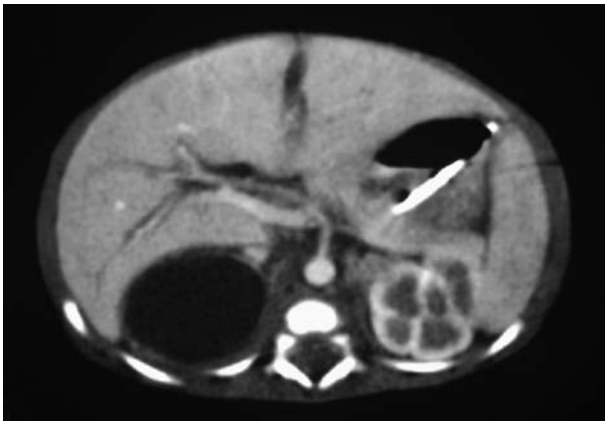

Figure 15.11 Contrast-enhanced CT on the same day as ultrasound Fig 15.9. In the right adrenal location, a non-enhancing low-density mass typical of an adrenal hematoma is apparent. Note that the septations are not apparent on the CT.

Calcified adrenal lesions

Adrenal calcification detected on abdominal imaging of a child has a broad differential diagnosis (Table 15.3) but it usually prompts investigations for a tumor, most commonly neuroblastoma.[33] The aforementioned affinity of neuroblastoma for skeletal tracer is independent of the presence of calcification, and its mechanism is unknown.[35] Ganglioneuromas and ganglioneuroblastomas can also calcify, and they are radiographically indistinguishable from neuroblastomas.

Granulomatous diseases often result in childhood adrenal calcification either unilaterally or bilaterally.[36–38] Distinguishing from the various granulomatous infections is impossible by imaging alone.

Wolman's disease is an uncommon autosomal recessive inborn error of metabolism leading to the accumulation of lipid in the abdominal organs. The condition is usually fatal by 6 months of age. On plain film the adrenal glands are enlarged and densely calcified. Ultrasound demonstrates concomitant hepatosplenomegaly. CT confirms the adrenal origin of the calcifications. MRI demonstrates the adrenal high signal intensity on T1 sequences due to lipid deposition.[39,40]

As mentioned above, perinatal adrenal hemorrhage can subsequently calcify. Imaging characteristics can vary from a peripheral rim of calcification to complete replacement of the gland. Incomplete resolution of hematoma can result in a peripherally calcified rim around a non-enhancing pseudocyst.[40]

Adrenal tumors and functional consequences

16

Julie Franc-Guimond and Anne-Marie Houle

Introduction

The pathogenesis, diagnosis, and management of adrenal tumors have recently evolved[1,2] mainly because of easier discovery of clinically silent, incidentally detected adrenal tumors using more sensitive imaging procedures such as computed tomography (CT) and magnetic resonance imaging (MRI).[3] Even if these tumors are rarely seen in children, it is important that the physician recognizes the clinical manifestations of these tumors as soon as possible, leading to an earlier diagnosis, prompt intervention, and improved survival.

Adrenal neoplasms

Although adrenal neoplasms in pediatrics are fortunately rare, representing less than 1% of all solid tumors, they may be potentially fatal. Tumors can arise from the medullary or the cortical portions of the adrenals and can be benign or malignant. Malignant cancers are rare, accounting for 0.05–0.2% of all cancers in the overall population, with an incidence of less than 2 new cases per million yearly.[4,5] Occurring at all ages,[6–11] adrenocortical carcinomas tend to present according to a bimodal age distribution, with the first peak occurring before age 5 years, and the second in the fourth to fifth decade.[12] Females clearly predominate in all series, accounting for 65–90% of the cases reported in the literature.[2] Even though some authors have reported a left-sided prevalence, others have not: bilaterality has been observed in 2–10% of cases.[2,9] Most adrenal masses found in children are functional, which renders the establishment of the diagnosis, as well as the medical and the surgical treatment, even more challenging.

Diseases of the adrenal cortex

Cortical tumors may be benign (adenoma, cyst, myolipoma) or malignant (adrenocortical carcinoma): all are rarely seen in children.[13–15] Furthermore, it may be very difficult to distinguish between them and the ultimate confirmation of the diagnosis is by histopathology; however, at times, the clinical outcome may not even correlate well with the histologic features.[16] The incidence of adrenocortical carcinomas is approximately 1 in 1.7 million in the general population.[17] They are seen in older patients compared with adenomas[18] and are more frequently encountered in females.[6] Moreover, they tend to be functional and may be part of hereditary syndromes. A retrospective review revealed that 92% of patients found to have a carcinoma presented with a mixed endocrine syndrome vs 32% of adenoma patients.[19] The latter commonly presented with a virilization syndrome only (92%).

Hormone-producing syndromes in patients with adrenal cortical neoplasms

Associated endocrine syndromes resulting from secretion of cortisol and/or adrenal androgens and their precursors, or, rarely, estrogen or mineralocorticoids, may be seen in patients with hormone-secreting adrenocortical neoplasms.

A more gradual onset of signs of hormone hypersecretion is generally observed in patients with adenomas, unlike those with adrenocortical carcinoma who tend to have a more acute and progressive course.

Cushing's syndrome

Cushing's syndrome in children is most commonly caused by an adrenocortical carcinoma and is seen in

one-third to one-half of these patients.[20] The classic Cushing's syndrome is a clinical disorder seen in cases of overproduction of cortisol, which leads to protein catabolism, subsequent increased glucogeneogenesis, and the typical symptoms associated with cortisol excess. Cushing's syndrome refers to patients presenting with the syndrome regardless of the cause; it differs from Cushing's disease which is caused by pituitary hypersecretion of adrenocorticotropic hormone (ACTH). One-fourth of the cases of endogenous Cushing's syndrome are caused by primary adrenal disease.

Aside from functional adrenocortical tumors and other usual causes, Cushing's syndrome can be particularly seen in children with primary pigmented nodular adrenocortical disease, which occurs as a component of Carney's complex. Also, infants found to have the McCune–Albright syndrome can present with ACTH-independent Cushing's syndrome with nodular hyperplasia or adenoma formation. Finally, islet cell carcinoma of the pancreas, neuroblastoma or ganglioneuroblastoma, hemangiopericytoma, Wilms' tumor, and thymic carcinoid can lead to ectopic production of ACTH in the pediatric population.

Pathophysiology

ACTH is secreted in response to corticotropin-releasing hormone (CRH) and vasopressin. It stimulates glucocorticoid cortisol secretion from the zona fasciculata and zona reticularis of the adrenal gland. Cortisol creates a negative feedback control on CRH, vasopressin, and ACTH. Cortisol is usually secreted in a circadian rhythm. Cushing's syndrome occurs when there is a loss of that rhythm, accompanied with a loss of the feedback mechanism of the hypothalamic–pituitary–adrenal axis, resulting in chronic exposure to excessive circulating cortisol levels.[21]

Clinical findings

Signs and symptoms associated with hypercortisolemia are variable; however, moon facies, truncal obesity, and typical evidence of Cushing's syndrome are generally obvious in children. More specifically, weight gain associated with growth retardation in the pediatric group should highlight the possibility of the diagnosis.[6] Other findings may include hirsutism, muscle weakness, bruising, vertebral fractures, hypertension, and diabetes mellitus, but these are rarely seen these days. Lethargy, depression, acne, and menstrual irregularity[22,23] could also be observed. Patients' photographs may help in showing the clinical progression to a Cushingoid state. In general, the findings are more obvious in infants than in older children.

Laboratory findings

The goal is to determine whether a patient has Cushing's syndrome rather than to identify the cause.[24] More specifically, Cushing's syndrome due to functioning adrenocortical tumors will exhibit elevated levels of several plasma and urinary steroids. These include cortisol following dexamethasone suppression test, dehydroepiandrosterone (DHEA) and its sulfate derivative (DHEAS), Δ^5-androstenediol, Δ^4-androstenedione, pregnenolone, 17-hydroxypregnenolone, and 11-deoxycortisol in the plasma, and free cortisol, 17-hydroxysteroids, 17-ketosteroids, and the tetrahydro metabolite of 11-deoxycortisol in the urine.[21] Measurements of other steroidogenic precursors, such as 17-hydroxyprogesterone and 11-deoxycortisol, may help if the presence of an adrenal malignancy in patients with Cushing's syndrome is suspected.[22] Autonomous activity of the adrenal glands will lead to a low plasma ACTH level, associated with elevated plasma cortisol concentration.

Tumor localization

Abdominal CT and/or MRI can document the existence of an adrenal lesion or bilateral nodular hyperplasia in cases of ACTH-dependent Cushing's syndrome. In patients with adrenal tumors, the contralateral adrenal should appear normal but could be atrophic since there is suppression of ACTH by the unilateral cortisol-secreting tumor.[25] Determining between adenomas and carcinomas is usually not feasible, but tumors >5 cm should be considered malignant until proven otherwise. Nevertheless, the ultimate confirmation of the diagnosis is histopathologic.[26,27]

Treatment

The treatment of Cushing's syndrome secondary to adrenal tumors is surgical. Adrenalectomy will either be performed unilaterally if there is a mass or bilaterally in patients with ACTH-dependent Cushing's syndrome not cured by other modalities. Preoperative preparation requires measures to correct the hypercortisolemia and its metabolic sequelae. Moreover, cortisol administration perioperatively should take place to prevent a state of hypoadrenalism. This would occur in cases of total bilateral adrenalectomy but also in cases of unilateral adrenalectomy, because the removal of the source of excessive cortisol in the

presence of an invariably atrophied contralateral gland will inevitably lead to temporary or permanent adrenal insufficiency.

Medical treatment is indicated in patients who cannot undergo surgery or in those who have had unsuccessful resection of their tumor (pituitary, ectopic, or adrenal) with or without metastatic spread. Metyrapone, ketoconazole, aminoglutethimide, mitotane, and etomidate have been used as inhibitors of steroid biosynthesis, and thus can be utilized in all cases of hypercortisolemia, regardless of cause, often with rapid improvement in the clinical features.

Prognosis

Removal of an adenoma offers an excellent prognosis, whereas the outlook for patients with malignant tumors is poor. Children tend to have a better prognosis, however.[28,29]

Virilizing adrenal tumors

Abnormal virilization is seen in cases of adrenocortical carcinomas in two-thirds of the adult patients,[30] whereas it is the most common hormonal syndrome in children with adrenocortical tumors.[2,8,10,31] Virilization is due to hypersecretion of adrenal androgens, including DHEA and its sulfate derivative DHEAS, Δ^5-androstenediol, and Δ^4-androstenedione, all of which may be converted to testosterone and 5α-dihydrotestosterone.

In adult females, the signs and symptoms include oligoamenorrhea, hirsutism, acne, excessive muscle mass, temporal balding, increased libido, and clitoromegaly. In young girls, precocious puberty occurs. Cushing's syndrome, combined with signs of virilization, is seen in 10–30% of all patients.[2,3,32]

Measurement of plasma adrenal androgens, testosterone, and 24-h urinary excretion of 17-ketosteroids may confirm the clinical diagnosis of adrenally induced virilization.

Feminizing adrenal tumors

Feminization seen as a single manifestation is quite rare. More commonly seen in males, feminization comes to one's attention because of newly observed gynecomastia and can be confirmed by measurements of elevated plasma estradiol and/or estrone.[33]

Aldosteronism

Aldosterone is the principal mineralocorticoid secreted by the adrenal gland. Increased secretion may be secondary to a primary defect (primary hyperaldosteronism) or result from factors that activate the renin–angiotensin system (secondary). Patients with primary hyperaldosteronism present with hypertension and/or hypokalemia; those with secondary do not. Primary aldosteronism will lead to a state of mineralocorticoid excess with low plasma renin activity (PRA). It may be caused by the following pathologies: an aldosterone-producing adenoma (APA), idiopathic bilateral (BAH) or unilateral (UAH) adrenal hyperplasia, glucocorticoid-remediable aldosteronism (GRA), or an aldosterone-producing adrenocortical carcinoma.

Although rare, unilateral APA has been described in children as young as 3.5 years and usually affects girls. Hypertension, hypokalemia, and metabolic alkalosis resulting from autonomous production of aldosterone by an adenoma was first reported by Conn in 1954. Since then, numerous studies have looked at the prevalence of primary aldosteronism and reported rates of between 0.05 and 14.4% among hypertensive individuals.[34–37] BAH tends to occur in older children and affects males more frequently. Primary aldosteronism due to UAH has been reported infrequently in the pediatric population.[38–41] Adrenal carcinomas, an exceedingly rare cause of primary aldosteronism, are usually large (>5 cm) at the time of diagnosis.

Other states of mineralocorticoid excess with low PRA may include cases of congenital adrenal hyperplasia or Liddle's syndrome.[42] In these two syndromes, non-aldosterone-mediated renal sodium reabsorption results in volume expansion and suppression of both PRA and plasma aldosterone (PA).

At the other end of the spectrum, other patients may present with a state of mineralocorticoid excess with high PRA. They may be hypertensive (renovascular disorders, coarctation of the aorta, renin-secreting tumors), normo- or hypotensive with reduced circulating blood volume (Gitelman's syndrome, Bartter syndrome, pseudohypoaldosteronism type I, diuretic use), or have reduced 'effective' circulating blood volume (congestive heart failure, hepatic cirrhosis, nephrotic syndrome).

Physiology of aldosterone regulation and action

Aldosterone synthesis is orchestrated by the renin–angiotensin system. Renin, produced in the juxtaglomerular apparatus, catalyzes the conversion of angiotensinogen to angiotensin I. Angiotensin I undergoes further enzymatic conversion by angiotensin-converting enzyme (ACE) to produce

angiotensin II, which acts to stimulate the production of aldosterone from the zona glomerulosa. The renin–angiotensin II system is also expressed locally and regulates aldosterone production in a paracrine fashion. Aldosterone's release is positively and directly modified by potassium balance. It can also be modulated by other factors such as ACTH, dopamine, and atrial natriuretic peptide.

Clinical findings

Signs and symptoms of hyperaldosteronism are nonspecific, often resulting in or associated with hypertension with headache, dizziness, and visual disturbances. However, some individuals have minimal blood pressure elevations and, as a result, hypertension is not a sine qua non for this disorder.[12] In fact, the most common finding remains hypokalemia. Chronic hypokalemia may lead to 'clear cell nephrosis', polyuria, nocturia, enuresis, and polydipsia. Muscle weakness and discomfort, tetany, intermittent paralysis, fatigue, and growth failure may also be observed in these children. Classic features of moderate-to-severe hypertension, hypokalemia, and metabolic alkalosis are highly suggestive of mineralocorticoid excess. However, only subtle clues of hyperaldosteronism exist in the majority of cases such as the recent onset of refractory hypertension.

Laboratory findings

Hyperaldosteronism can generally be proven by measurements of aldosterone and PRA, 11-deoxycorticosterone and/or corticosterone, respectively. Plasma and urine levels of aldosterone are increased, and plasma levels of renin are persistently low.[43–45] In addition, the serum pH, carbon dioxide content, and sodium concentrations may be increased and the serum chloride and magnesium levels decreased. Serum levels of calcium are normal, even in children who manifest tetany. The urine is neutral or alkaline, and kaliuresis is present. Aldosterone does not decrease with sodium chloride administration and renin does not respond to salt and fluid restriction.

Differential diagnosis and tumor localization

All cases with a history of hypertension associated with 'spontaneous' or severe hypokalemia precipitated by diuretic therapy should suggest the diagnosis of primary aldosteronism. Suspicion is also warranted in all incidentally discovered adrenal masses, especially in a hypertensive individual.[46] Once the diagnosis is established, it is necessary to identify the underlying cause (APA, BAH, UAH, GRA, or an aldosterone-producing adrenocortical carcinoma).

All children should have a therapeutic trial with daily administration of dexamethasone before invasive studies are carried out, since this test is easy to perform. A marked suppression of aldosterone and disappearance of hypertension is observed in patients with the glucocorticoid-suppressible variant of hyperaldosteronism or GRA.

If there is no response, CT scanning or MRI may reveal a mass within the adrenal. In cases of inconclusive data or equivocal radiographic features, however, adrenal vein sampling of aldosterone and cortisol is recommended to differentiate between an adenoma and hyperplasia.[47–50]

Treatment

GRA is managed by daily administration of glucocorticoid. The treatment of an APA is surgical. Resection cures or ameliorates hypertension and invariably treats the hypokalemia. In one recent analysis, however, only one-third of patients became normotensive postoperatively.[51] In patients known to have an APA, suppression of aldosterone secretion in the contralateral adrenal gland is expected, thus resulting in a transient hyporeninemic hypoaldosterone state.[52] Therefore, sodium restriction could increase the risk of dehydration. Pharmacologic treatment of BAH with spironolactone or amiloride usually results in normalization of the blood pressure and serum potassium levels. Management of secondary hyperaldosteronism is directed toward the specific causative disorder.

Hereditary syndromes associated with adrenocortical tumor formation

Adrenocortical tumors have been associated with several genetic syndromes, which explains the origin of the familial adrenocortical tumors and the unusual associations with other tumors and/or conditions.[2] Among many, the multiple endocrine neoplasia type 1 (MEN 1) and the Beckwith–Wiedemann syndrome are the ones most commonly mentioned. The clinical features associated with MEN 1 are hyperparathyroidism and pancreatic–duodenal and pituitary tumors. The chromosomal anomalies are mutations at locus 11q13,[53,54] whereas the chromosomal defect found in the Beckwith–Wiedemann syndrome (neonatal macrosomia, macroglossia, and omphalocele) is an allelic loss of 11q15. Other syndromes associated with benign and/or malignant adrenocortical neoplasms include Carney's complex, congenital

adrenal hyperplasia, Li-Fraumeni syndrome and McCune–Albright syndrome.

Diseases of the adrenal medulla

Pheochromocytoma

Pheochromocytomas are catecholamine-secreting tumors. Ninety percent arise from the medullary portion of the adrenals, whereas 10% occur in extra-adrenal chromaffin tissues (paragangliomas). About 10% are familial, multicentric, and bilateral, whereas the remainder are sporadic. The incidence in the hypertensive population varies between 0.05 and 0.1%.

Pheochromocytomas are uncommonly observed in children and the true incidence is unknown. Indeed, it appears that this tumor of neuroectodermal origin is more common in adults, and most data on its behavior and management have been obtained from the adult population. In comparison with the findings observed in adults, known facts regarding pheochromocytomas in children include an age at presentation of around 10 years, a male propensity in most series, an increased incidence of bilaterality (20%) and multifocality, a lower incidence of malignancy (2.4–3.5%), and a greater tendency for familial occurrence.[55]

Familial pheochromocytomas can occur with or without an association to known familial cancer syndromes (MEN 2, von Hippel–Lindau disease, neurofibromatosis type 1, Sturge–Weber syndrome, and familial carotid body tumors).[56] It appears that hereditary forms can evolve differently in terms of tumor growth rate and malignancy potential. Thus, individuals with familial pheochromocytomas are diagnosed at a younger age and tend to have bilateral or multifocal lesions that are usually benign.

Signs and symptoms

Signs and symptoms are related to excessive secretion of catecholamines produced in large amounts by pheochromocytes. Hypertension is the most common sign and it is more frequently sustained in young subjects rather than paroxysmal. Other signs and symptoms could include postural hypotension, headaches, increased sweating, pallor, flushing, tachycardia, weight loss, constipation, weakness, and visual complaints. Headaches, nausea, vomiting, constipation, weight loss, and visual complaints are frequently observed in children.[57,58] A palpable mass could also be present and in combination with sustained hypertension should strongly suggest the diagnosis. Nonetheless, a palpable mass could be the sole finding.

Diagnosis

The biochemical diagnosis is achieved from measurements of catecholamines and catecholamine metabolites in plasma or urine.[59–63] Norepinephrine and epinephrine are ubiquitously produced by the sympathoneuronal and sympathomedullary systems and, therefore, are not specific to pheochromocytomas. Other limitations relate to the fact that increased plasma catecholamine levels may be produced by a variety of conditions (e.g. emotional stress, physical activity, eating, fever), that in some patients pheochromocytomas may not secrete catecholamines, or that many pheochromocytomas secrete episodically. Glucagon stimulation and clonidine suppression tests are useful in some patients to further confirm the diagnosis of pheochromocytoma.[57,64,65]

Tumor localization

Pheochromocytomas can be imaged with CT, MRI, and/or scintigraphy after administration of ^{131}I- or ^{123}I-labeled metaiodobenzylguanidine (MIBG).[66–69] If an initial abdominal CT or MRI is positive, whole-body MIBG should be performed to confirm the diagnosis. If abdominal studies are negative, then whole-body evaluation by CT or MRI is indicated. If an initial MIBG scan is positive, then CT or MRI follows to precisely localize a mass. However, a negative MIBG scan does not exclude a pheochromocytoma. More recently, positron emission tomography (PET) has been used in particular cases.

Treatment

The definitive treatment is surgical excision of the tumor. Of particular interest, patients with pheochromocytomas should undergo pharmacologic blockade (α and β) of catecholamine effects and synthesis prior to surgery as well as aggressive correction of the hypovolemia perioperatively to avoid hypotension. Intra-adrenal pheochromocytomas can be removed successfully by laparoscopy, which minimizes catecholamine-induced hemodynamic changes during operation.[70]

The neuroblastic tumors

Neuroblastic tumors include ganglioneuroma, ganglioneuroblastoma, and neuroblastoma, which are

tumors of the sympathetic nervous system.[71] They arise wherever sympathetic tissue exists and are found in the neck, posterior mediastinum, adrenal gland, retroperitoneum, and pelvis. The adrenal gland is the most common site; hence the need to discuss these pathologies.

The most benign tumor is the ganglioneuroma, which is composed of gangliocytes and mature stroma.[72,73] It arises from the medulla in less than half of the cases found to have an abdominal ganglioneuroma.[74–77] Patients of all ages are affected, predominantly children and young adults (42–60% of cases)[78–81] and they are often asymptomatic. Otherwise, abdominal pain or an abdominal mass is the most common finding.[79] Hormonally active tumors have been reported, and the secretion of catecholamines, vasoactive intestinal polypeptides, or androgenic hormones explains such symptoms as hypertension, diarrhea, and virilization.[78–80,82–84] The prognosis is excellent, and recurrence is rare after surgical removal.[79,85]

Ganglioneuroblastomas are transitional tumors of sympathetic cell origin that contain elements of both malignant neuroblastoma and benign ganglioneuroma. The most common tumor location is the abdomen. This tumor is most often seen in patients 2–4 years old and is rarely seen after 10 years.[86] The prognosis and response to therapy are significantly more favorable than with neuroblastomas.[87]

Neuroblastoma is the most immature, undifferentiated, and malignant tumor of the three that consist of primitive neuroblasts.[88] Neuroblastoma, however, may have a relatively benign evolution, even when metastatic. It is the third most frequent neoplasm in children after leukemia and central nervous system tumors.

These tumors are predominantly found in boys <10 years of age. Furthermore, approximately 80% of these neoplasms are found in children under the age of 5 years, with a median age of 22 months.[88] Two-thirds of neuroblastomas are located in the abdomen, and approximately two-thirds of these arise in the adrenal gland. The remaining ones originate in the paravertebral sympathetic chain or presacral area or organ of Zuckerkandl.[89] Neuroblastomas metastasize to bone, bone marrow, liver, lymph nodes, and skin and 35–70% of the cases have systemic disease when diagnosed.[88,90–96]

These tumors can also be observed in newborns or fetuses, as prenatal sonography may allow antenatal diagnosis.[86] In fact, neuroblastoma is the most common malignancy in the first month of life, accounting for 30–50% of all malignant tumors at this age. Both fetal and neonatal neuroblastomas have very good prognoses but differ somewhat in their patterns of metastatic spread and organ of origin.[97,98] Neonatal neuroblastoma has an adrenal origin in 45% of patients and 60% have metastases at the time of diagnosis, mostly to the liver, bone cortex, marrow, and skin. Tumor biologic behavior is usually favorable, and the survival rate is greater than 90%. However, mortality may occur, and is often caused by respiratory insufficiency from massive hepatic metastases.[97] Fetal neuroblastoma has been discovered as early as 19 weeks, although the mean age at discovery is 36 weeks.[98] It is almost always (90% of cases) of adrenal origin. It presents with hepatic and, less commonly, marrow metastases. An almost universally good outcome is expected and a conservative approach is advocated.[98] Because approximately 90% of neuroblastomas and ganglioneuroblastomas secrete vanillylmandelic acid (VMA) and homovanillic acid (HVA), screening of urinary catecholamines via urine assay grew in popularity in an attempt to improve outcome. Screening began in Japan in 1973 in 6-month-old infants. Unfortunately, epidemiologic analysis showed that the incidence in older children did not change, and that the tumors discovered at screening were of low stage and favorable histologic characteristics, suggesting that the tumors discovered via urinary screening were those likely to remain occult, regress, or mature. Other studies done in Quebec have shown similar data.[99] Therefore, it appears that screening in infancy does not reduce the incidence of advanced-stage disease in older children, nor does it increase survival in younger patients with more aggressive tumors. The value of screening after 1 year of age or later is unknown.[100,101]

The most frequent clinical finding observed in the presence of a neuroblastoma is abdominal pain followed by abdominal distention. Other symptoms include malaise, irritability, weight loss, shortness of breath, and peripheral neurologic deficit.[90] Of interest, neuroblastic tumors may rarely occur in combination with von Recklinghausen's disease, Beckwith–Wiedemann syndrome, Hirschsprung's disease, central failure of ventilation, or DiGeorge syndrome.[87,88,102]

Two classification systems are commonly used in North America to differentiate neuroblastic tumors into risk groups: the Shimada classification and the Pediatric Oncology Group (POG) classification. Both systems assess histologic features, such as cellular differentiation, to determine prognosis. The POG system is based solely on the degree of differentiation of the

different histologic elements.[103,104] The Shimada classification combines histologic features and patient age at diagnosis.[105] The degree of cellular and extracellular maturation between the three tumors varies tremendously; immature tumors tend to be aggressive and occur in youngsters (median age under 2 years), whereas mature tumors occur in older patients (median age approximately 7 years) and tend to have a more benign behavior.[71] Also, prognosis varies according to additional features such as DNA content, tumor proto-oncogenes, and catecholamine synthesis. Also, another stratification tool, based on clinical, radiologic, and surgical features, was developed in 1986 by an international consensus group, the International Neuroblastoma Staging System (INSS).[106,107]

Treatment consists of surgery and, usually, chemotherapy. Radiation therapy may also be used. Children with low- or intermediate-risk tumors have a relatively good prognosis but, despite recent advances in treatment, including bone marrow transplantation, neuroblastoma remains a lethal tumor, accounting for 15% of cancer deaths in children.[108,109] More specifically, even with aggressive treatment of the high-risk tumors, the 3-year event-free survival rate for these patients is less than 15%[108] but improved 2-year survival after bone marrow transplantation has been documented in some studies; prolonged survival is currently being assessed.[109]

Surgery of the adrenal

17

Stephen Boorjian, Michael Schwartz, and Dix P Poppas

Background

In 1936, Hugh Hampton Young described bilateral subtotal adrenalectomy for children with congenital adrenal hyperplasia (CAH).[1] Since that time, the physiology and pathophysiology of the adrenal gland has become increasingly understood, while imaging of the adrenal to localize disease processes has improved. These advancements have helped to define the role of surgery in the management of adrenal disorders. The spectrum of pediatric adrenal disease, as well as the pathophysiology of these processes, has been covered in the preceding chapters. Here, we focus primarily on the surgical management of adrenal disease. Specific pathologic conditions are addressed with regard to their influence on surgical approach.

Laparoscopic adrenalectomy

Since the first description of laparoscopic adrenalectomy by Gagner et al in 1992, the advantages of the laparoscopic approach have been well documented in the adult population, including shorter hospital stay, decreased postoperative pain, quicker return to preoperative activity level, and improved cosmesis.[2–6] However, there has been a relative delay in the application of laparoscopic adrenalectomy to the pediatric population. This delay has resulted in part from the higher incidence of malignant adrenal tumors among children compared with adults.[7–9] In addition, neuroblastoma, which represents the most common adrenal tumor in children, is characterized by an infiltrative growth pattern that has traditionally been seen as a contraindication to laparoscopic excision. Nevertheless, the growing experience with laparoscopy and the continued improvements in surgical instrumentation have fostered a trend toward increased use of minimally invasive techniques in pediatric adrenal surgery. To date, laparoscopic adrenalectomy has been reported for a variety of adrenal pathologies in children, including adrenal adenoma, carcinoma, hyperplasia, pheochromocytoma, and, more recently, select cases of neuroblastoma as well.[9–12]

The approach to laparoscopic adrenalectomy may be either transperitoneal or retroperitoneal. In both of these techniques, the central tenet of the procedure is to dissect the adrenal gland from the surrounding tissue with minimal manipulation of the gland itself; in essence, to remove the patient from the adrenal gland.[13]

Transperitoneal laparoscopic adrenalectomy

Patients are placed on a clear liquid diet on the day before surgery, and are given a mechanical bowel preparation. After general anesthesia is established, a Foley catheter is inserted into the bladder, and the stomach is decompressed with an oral gastric tube. We place the patient in the semilateral decubitus position, with the side of the lesion elevated approximately 45°, and flex the operating table. The patient is draped from the nipple line to the lower abdomen and across the midline, allowing for possible open conversion. The patient is rolled to a near-supine position, and pneumoperitoneum is established. We prefer the Hasson open cutdown technique for establishing pneumoperitoneum in the pediatric population. The first trocar, an 11–12 mm trocar, is placed in the midline just above the umbilicus. The peritoneal space is insufflated to 12–15 mmHg using CO_2, and the abdominal cavity is explored with a 10 mm, 30° laparoscope. The table is then rolled to a full flank position for additional trocar placement.

For left adrenalectomy, two accessory trocars are inserted: a 5 mm port 3–4 cm cephalad to the supraumbilical trocar, and a 5 mm port in the midclavicular line, below the costal margin (Figure 17.1). Port placement may vary slightly with the age and size of the child. Adhesions of the left upper quadrant to the anterior abdominal wall are first identified and

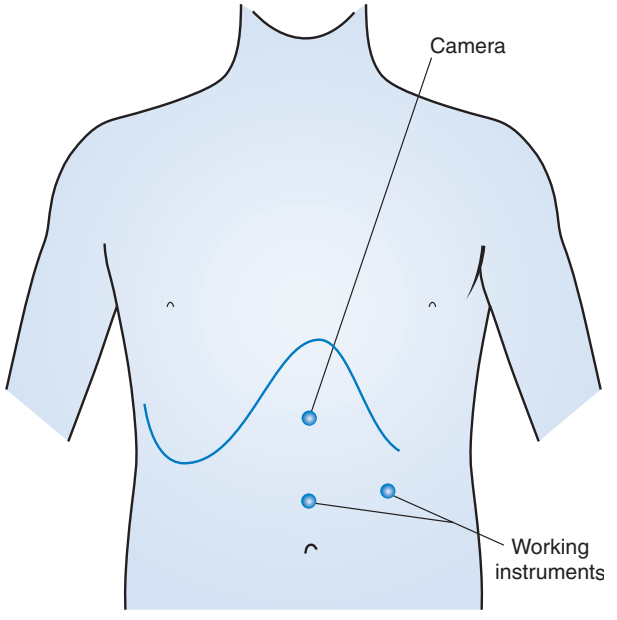

Figure 17.1 Port placement for transperitoneal laparoscopic left adrenalectomy. The supraumbilical working instrument trocar is 11–12 mm, to facilitate insertion of a clip applier.

incised using the harmonic scalpel. The splenic flexure of the left colon is then mobilized by incising the peritoneum along the line of Toldt. The spleen is mobilized by incising its attachments to Gerota's fascia, abdominal side wall, and diaphragm with the harmonic scalpel or electrocautery shears. Dissection of the lateral splenic attachments is carried out until the gastric fundus is visualized. At the conclusion of this dissection, the spleen should fall medially without the need for retraction.

Once the splenic flexure and spleen are mobilized, the plane between the tail of the pancreas and Gerota's fascia is developed to release the pancreas medially. The superior border of the adrenal gland is then dissected from lateral to medial. The inferior phrenic vessels are identified, clipped, and divided as they are encountered along the upper aspect of the adrenal. The lateral-most attachments of the gland are left intact to hold the gland in place, and thereby facilitate the remainder of the dissection. Dissection is carried medially along the gland, where the arterial supply to the adrenal from the aorta is encountered, clipped, and divided. Inferiorly, the left adrenal vein is identified entering the left renal vein, clipped, and divided.

Division of the left adrenal vein often reveals an inferior adrenal artery arising from the left renal artery; if encountered, this artery should be clipped and divided. Finally, the lateral attachments of the adrenal are divided, releasing the gland. The adrenal is placed in a retrieval bag inserted through the umbilical port. Visualization for the remainder of the procedure is accomplished with a 5 mm, 30° scope placed through the port in the midclavicular line. The bag containing the specimen is temporarily placed on the kidney, and the operative bed irrigated and inspected for bleeding. Once hemostasis is ensured, the specimen is then removed from the patient; the trocar site may be enlarged if necessary to facilitate the removal of larger glands. The remaining ports are then removed and closed.

Laparoscopic right adrenalectomy is performed using three accessory trocars, because of the need to retract the liver. After insufflation, a 5 mm port is placed 3–4 cm cephalad to the supraumbilical trocar (as for left adrenalectomy above), while two 5 mm ports are placed laterally, below the costal margin in the anterior axillary and midclavicular lines (Figure 17.2). After adhesions of the right upper quadrant to the anterior abdominal wall are incised, the liver is mobilized from the abdominal side wall and diaphragm by incising the triangular and coronary ligaments. The extent of mobilization of the liver necessary for exposure increases with age in children, as the distance between structures increases and the flexibility of tissues decreases. A liver retractor is then introduced through the anterior axillary line trocar to reflect the liver away from the adrenal (see Figure 17.2).

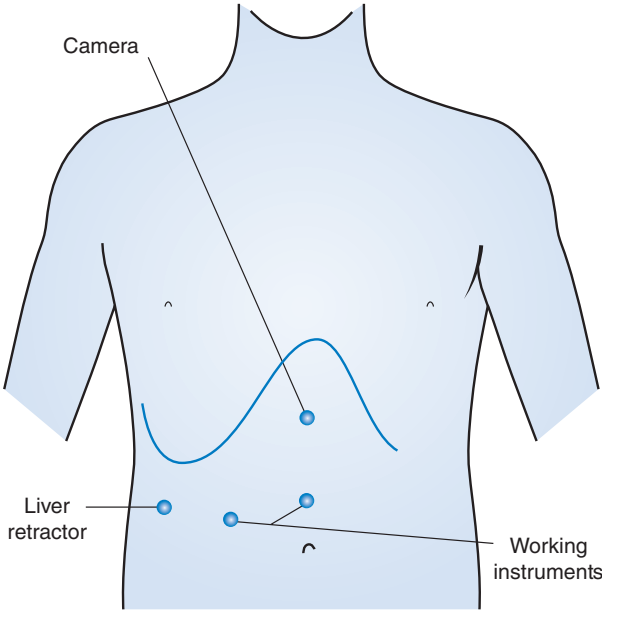

Figure 17.2 Port placement for transperitoneal laparoscopic right adrenalectomy. Note additional trocar in anterior axillary line for liver retractor.

With the liver mobilized, the anterior wall of the vena cava is identified, and the medial attachments of the adrenal gland are released. The duodenum is mobilized medially, exposing the renal hilum. As the dissection is carried cephalad on the anterior wall of the cava, the right adrenal vein is identified. We secure the vein by doubly clipping both the patient and specimen sides of the vein and then sharply dividing the vein between the clips (Figure 17.3).

Once the adrenal vein has been controlled, the superior and inferior aspects of the adrenal are sequentially dissected as for a left adrenalectomy, dividing the inferior phrenic vessels on the cephalad border and the inferior vascularized pedicle, which arises from the right renal hilum, on the caudal border of the gland. The adrenal gland is then mobilized off the upper pole of the kidney by incising Gerota's fascia at the junction of the upper pole and the adrenal using the harmonic scalpel. The lateral attachments, left intact to maintain the gland in position for dissection, are released last, and the adrenal removed.

Postoperatively, patients are started on clear liquids on the night of surgery, and their diet is advanced as tolerated. The Foley catheter is removed on the first postoperative day, and patients are typically discharged after passing a trial of voiding.

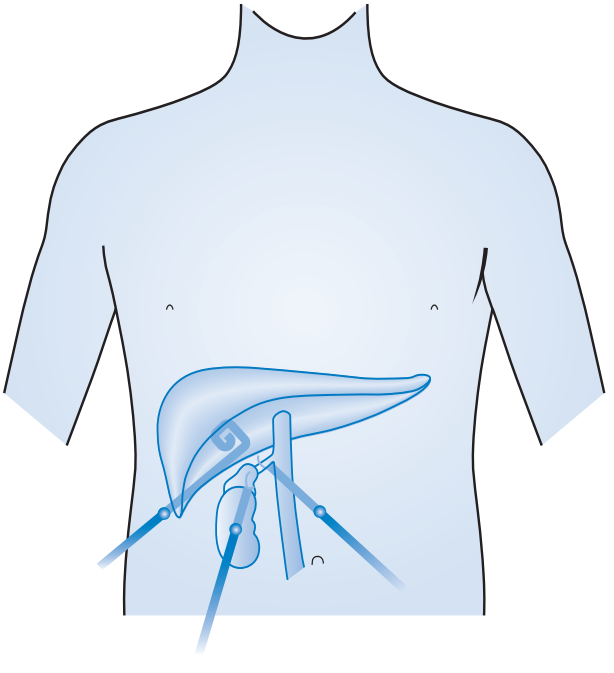

Figure 17.3 Transperitoneal laparoscopic exposure and ligation of the right adrenal vein. The camera port is not shown.

Retroperitoneal laparoscopic adrenalectomy

Since its description by Gaur in 1992, retroperitoneal laparoscopy has been well described for a variety of procedures, including adrenalectomy, in adults.[14] Proponents of the retroperitoneal laparoscopic approach argue that this technique offers a more direct access to the adrenals, without the need for dissection and retraction of intra-abdominal organs. This approach may be particularly suited for patients with a history of abdominal trauma or surgery, in whom dense intra-abdominal adhesions may be anticipated. In addition, by not opening the peritoneum, postoperative intestinal complications are potentially avoided.[15] Disadvantages of retroperitoneal laparoscopy include a limited working space, which is a particular challenge in the pediatric patient population.[16] To date, the application of retroperitoneal laparoscopic adrenalectomy in children has been limited. One study reported on 3 cases of retroperitoneal laparoscopic adrenalectomy in children, with one open conversion, while a second study reported on 10 cases without an open conversion.[17,18] As the experience with pediatric retroperitoneal laparoscopic nephrectomy becomes more widespread, however, and its efficacy and safety confirmed, the application of retroperitoneal adrenalectomy will probably increase as well.[16,19–22]

We position the patient in flank position, and gain initial access through an incision below the tip of the 12th rib, just superior to the anterior iliac spine. Dissection is carried bluntly through the external and internal oblique muscles and the transversus abdominus muscle into the retroperitoneum. The peritoneum is swept medially, and a working space in the retroperitoneum is established using balloon distention. We prefer fashioning a balloon for distention by securing the finger of a surgeon's glove to a 16 Fr red rubber catheter. Once the balloon is introduced into the retroperitoneal space, the glove tip is filled with 100–500 ml of saline and left inflated for 5 minutes to develop the retroperitoneal space. The balloon is then removed, a 10 mm Hasson trocar is introduced into the space, and pneumoretroperitoneum established to a pressure of 12 mmHg. Two additional 5 mm trocars are placed in the posterior and anterior axillary lines, superior to the Hasson trocar.

For right adrenalectomy, the vena cava is identified medial to the psoas muscle, and dissection is carried superiorly along the vena cava to identify first the renal hilum and then the right adrenal vein, which is

ligated using hemoclips. The medial and inferior margins of the adrenal are dissected, dividing the adrenal arteries with the harmonic scalpel or clips as they are encountered. The superior aspect of the gland is mobilized as well, and the adrenal is then dissected free from the upper pole of the kidney. As with the transperitoneal laparoscopic adrenalectomy, the lateral attachments of the gland are released last, and the adrenal is removed.

The initial dissection for a retroperitoneal laparoscopic left adrenalectomy identifies the renal hilum. The left renal artery is retracted inferiorly, revealing the adrenal vein as it enters the left renal vein. The adrenal vein is ligated with hemoclips and divided. The adrenal gland is then dissected along its perimeter, using the harmonic scalpel and hemoclips as needed. For a left-sided retroperitoneal laparoscopic adrenalectomy, the medial attachments of the gland are left intact to facilitate dissection, while the superior, lateral, and inferior mobilization of the adrenal is completed. The medial attachments are released last, and the specimen extracted.

Results of laparoscopic adrenalectomy

There are no prospective studies in the pediatric population comparing laparoscopic versus open adrenalectomy. A recent retrospective analysis of adrenalectomy in children found a shorter hospitalization, decreased postoperative pain, more rapid return to preoperative activity level, and improved cosmesis in the laparoscopic cohort.[23] Moreover, a number of studies have confirmed the safety and efficacy of laparoscopic adrenalectomy in children (Table 17.1).[9–11]

Although no absolute upper limit has been set on the size of adrenal tumors that can be removed laparoscopically, larger tumors, especially of the right adrenal gland where lesions may grow behind the vena cava, present a greater technical challenge and increased operative risk. These lesions should be assessed on an individual basis, taking into account the likely tumor pathology as well as the surgeon's experience. In particular, tumors with clear evidence of local extension, requiring en bloc resection of adjacent organs, should be managed with open resection.

Open adrenalectomy

Given that the role of laparoscopic adrenalectomy in the pediatric population is still evolving, as well as the predominance of neuroblastomas (many of which may not be amenable to the laparoscopic resection) among adrenal lesions in children, pediatric urologists should be familiar with the various open approaches to adrenalectomy as well. As with laparoscopy, the central principle of open adrenal surgery is to dissect the patient from the tumor, with minimal manipulation of the gland.

Flank approach

The standard extrapleural, extraperitoneal flank approach to the adrenal gland may be performed for either left or right adrenalectomy. This technique offers the advantage of utilizing the positioning and initial exposure (Figure 17.4) familiar to urologists from radical nephrectomies. For right adrenalectomy, the retroperitoneal space is first identified by medial reflection of the colon and duodenum. The liver is dissected off the anterior surface of the adrenal, allowing ligation of the superior vasculature to the gland. This dissection is facilitated by inferior traction on the kidney, and the mobilization is continued along the posterior abdominal wall and diaphragm from lateral to medial. The small arterial branches to the adrenal should be divided with hemoclips as they are encountered. The inferior vena cava is then exposed, and the adrenal vein identified, dissected free, and divided with clips or ties. The inferior attachments of the adrenal to the kidney are released last, allowing removal of the gland.

Mobilization for left adrenalectomy begins with

Table 17.1 Published series of laparoscopic adrenalectomy in children

Study	No. of patients	Age (mean)	Lesion size (mean)	Hospital stay (mean)	Operative time (mean)	Rate of open conversion
Miller et al[10]	17	9.8 years	4.8 cm	1.5 days	120 min	5.8%
Castilho et al[11]	13	6.3 years	4.1 cm	5.5 days	107 min	15.4%
Kadamba et al[9]	10	4 years	5.3 cm	3 days	143 min	20%

division of the splenorenal ligament. Gerota's fascia can be swept medially, and the pancreas retracted superiorly and medially, exposing the adrenal. The superior attachments of the adrenal are released from lateral to medial, leading to the renal hilum. The adrenal vein is isolated at its entry to the renal vein, where it is divided. The inferior aspect of the gland is dissected off the upper pole of the left kidney, and the gland is then removed.

Thoracoabdominal adrenalectomy

The main indication for a thoracoabdominal approach to the adrenal gland is to provide maximum exposure for large tumors, particularly on the right side where the liver and vena cava can impede exposure. However, this technique may increase pulmonary complications, as the diaphragm is divided and the thoracic cavity entered.[24] The patient is positioned in approximately 45° flank, and the incision is made through either the 8th or 9th intercostal space (Figure 17.5). The intercostal muscles are encountered and divided, revealing the muscle fibers of the diaphragm, which are circumferentially divided. Adrenalectomy is then performed as described above for the flank approach. At the conclusion of the procedure, a thoracostomy tube is placed in the ipsilateral hemithorax, and the diaphragm is closed using interrupted silk sutures.

Posterior adrenalectomy

Currently, we use the open posterior approach to adrenalectomy primarily for simultaneous bilateral adrenalectomy: for example, in patients with Cushing's disease.[24] Patients are placed in the prone position, and an oblique incision is made overlying the 11th or 12th ribs (Figure 17.6). After subperiosteal

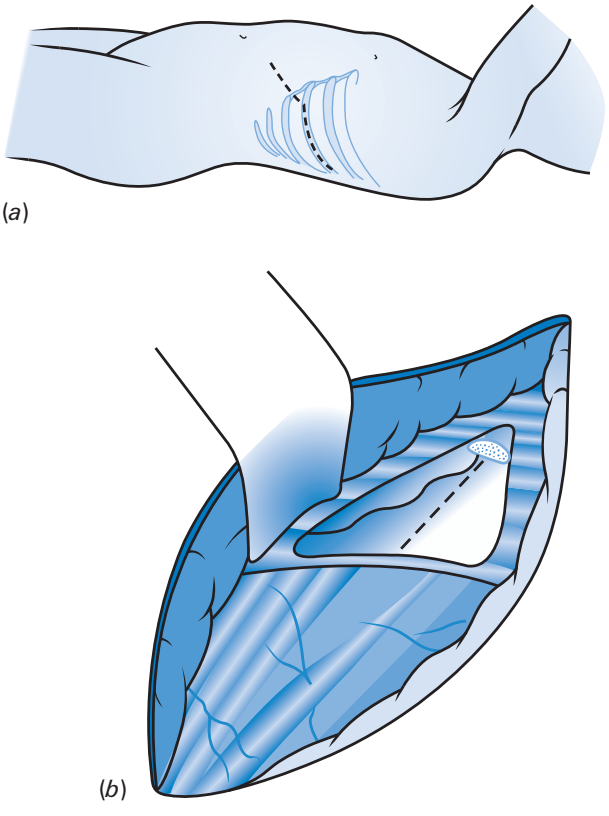

Figure 17.5 (*a*) Incision overlying 9th rib for thoracoabdominal left adrenalectomy. (*b*) Exposure after resection of rib (seen cut at top of figure). Dotted line marks incision in diaphragm muscle.

rib resection, the diaphragm and pleura are mobilized superiorly to expose the retroperitoneal space. For left adrenalectomy, the splenorenal ligament is first released laterally, and dissection then proceeds on the superior aspect of the gland from lateral to medial. This dissection may be facilitated by downward manual traction on the kidney. Medially, the left adrenal vein is identified and divided with clips or ties at its insertion to the left renal vein. Dissection is completed along the inferior aspect of the gland, and the adrenal is removed.

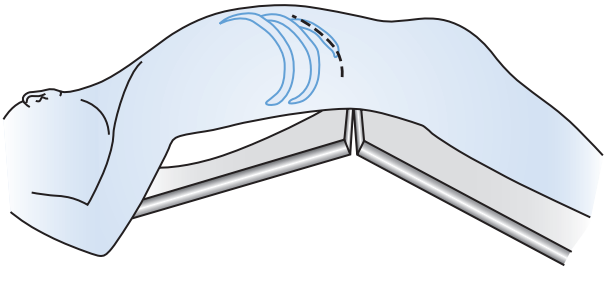

Figure 17.6 Positioning for (standard) posterior approach to adrenalectomy. Dotted line marks incision.

For a posterior right adrenalectomy, the liver is initially dissected off the adrenal and retracted cephalad. The superior vascular attachments of the gland are then divided from lateral to medial, until the vena cava is exposed. The lateral wall of the vena cava is dissected to the origin of the right adrenal vein, which can be clipped or tied and divided. After division of the vein, the inferior attachments of the gland are released, and the adrenal is removed. Given the often difficult exposure of the right adrenal vein through this (standard) posterior approach, we perform open right adrenalectomy via a modified posterior approach, where the patient's position on the operating table approximates that used during a Gil–Vernet dorsal lombotomy incision (Figure 17.7).[25] An 11th or 12th rib incision is made, and the liver is mobilized as described above. However, as the vena cava is exposed by division of the superior attachments of the gland, the adrenal vein is encountered coursing toward the operating surgeon (see Figure 17.7), thereby facilitating its identification and division. In the (standard) posterior approach, the vein lies in a posterior position and is thus at risk of avulsion during exposure.[15] The remainder of the dissection proceeds as for the standard posterior approach.

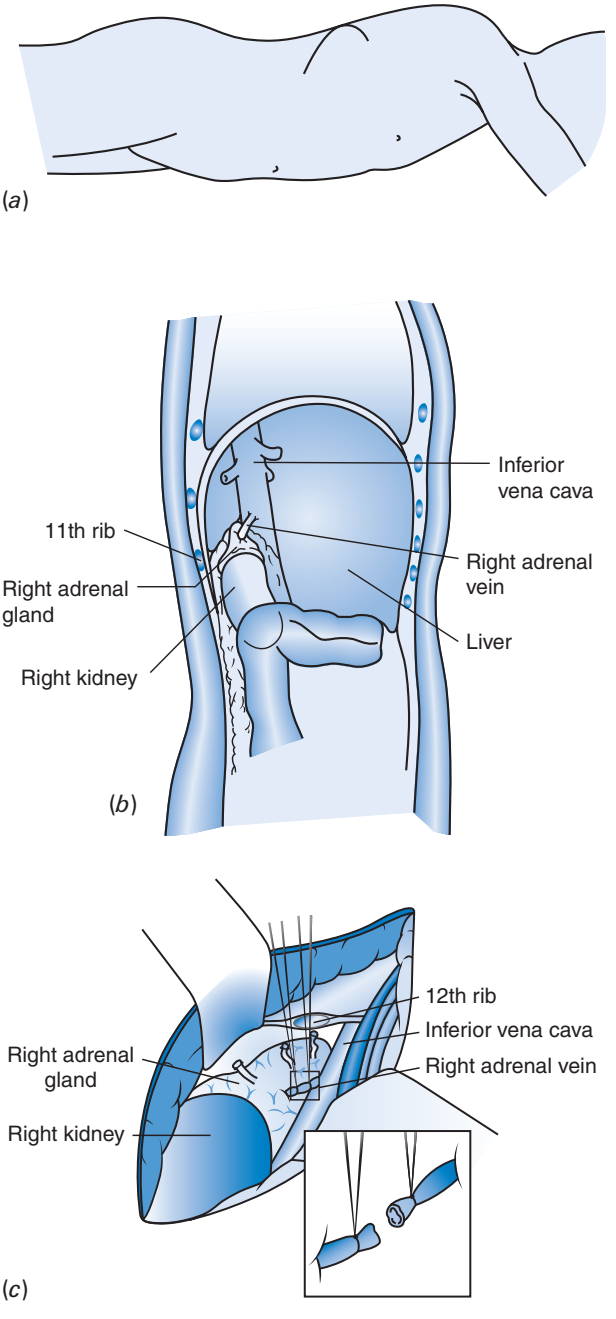

Figure 17.7 Modified posterior right adrenalectomy. (*a*) Positioning and incision. (*b*) View of adrenal bed, with right adrenal vein visible, seen during this approach. (*c*) Exposure and division of right adrenal vein.

Transabdominal adrenalectomy

Transabdominal adrenalectomy is indicated primarily to facilitate complete abdominal exploration, as in the case of multiple pheochromocytomas, patients with large adrenal carcinomas, and for adrenal lesions with involvement of the inferior vena cava. A chevron incision is used to gain access to the peritoneum (Figure 17.8), which is then systematically explored for lesions and/or metastases. Once this has been accomplished, right adrenalectomy may be performed by reflection of the hepatic flexure of the colon inferiorly and incision in the posterior peritoneum lateral to the kidney. This allows reflection of the liver superiorly and exposes the anterior vena cava, approximately at the level of the renal hilum. Cephalad dissection along the anterolateral wall of the vena cava leads to the right adrenal vein, which is then divided. The superior vasculature of the adrenal is released next, proceeding from medial to lateral and facilitated by downward manual traction on the kidney. Lastly, the inferior attachments of the adrenal to the right kidney are mobilized.

For left adrenalectomy, the colon is first reflected medially, and the renal hilum identified and dissected. The left adrenal vein is divided as it enters the left renal vein. The anterior adrenal surface is then exposed by mobilization of the pancreas and spleen. The remainder of the dissection proceeds from medial to lateral along the superior and inferior borders of the gland.

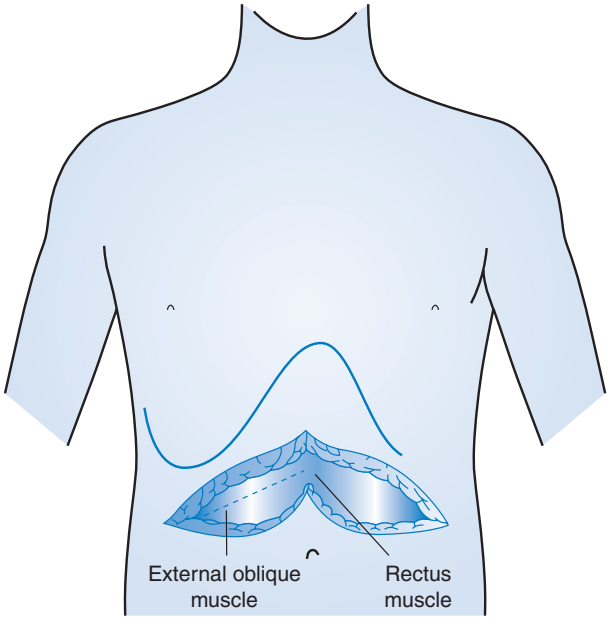

Figure 17.8 Chevron incision for transabdominal adrenalectomy. While such an incision facilitates exposure of both adrenal glands and abdominal exploration for metastases, improved imaging has increased the capacity for precise preoperative localization of lesions. In such cases, the incision can be limited on the contralateral side.

Complications of adrenal surgery

Bleeding may be encountered during either open or laparoscopic adrenalectomy. When operating on the left adrenal, particular care should be taken to avoid injury to Belsey's artery, a communicating branch between the left gastric and the inferior phrenic arteries. This vessel lies close to the esophageal hiatus, and is often accompanied by a phrenic vein.[26] When encountered, Belsey's artery, as well as any associated phrenic vessels, should be ligated to prevent avulsion.

Injury to adjacent organs may also occur during adrenalectomy, most commonly to the diaphragm and pleura. If recognized intraoperatively, the injury may be repaired without the need for thoracostomy tube placement. If such an injury occurs during open adrenalectomy, a red rubber catheter is placed through the defect, with the other end draining into a container of water. The defect is closed with a purse-string chromic suture during hyperinflation of the lung once no bubbles are seen exiting the water end of the catheter. The catheter is removed immediately prior to tightening the purse-string suture. Laparoscopic identification and suture repair of diaphragmatic injuries have also been reported.[27] In any case of diaphragmatic injury, a chest radiograph should be obtained postoperatively to evaluate for pneumothorax, and a thoracostomy tube may be placed at that time if necessary. Other adjacent organ injuries which may occur during adrenalectomy include capsular tears of the liver or spleen, which usually can be managed with a combination of manual tamponade, argon beam coagulation, and hemostatic gel packing.

Complications specific to the laparoscopic approach include trocar injury during placement and port-site hernia. Passage of trocars should be done under direct vision; if inadvertent organ injury is suspected, close inspection and repair should be performed. Moreover, when exchanging instruments during the case, they should be passed under direct visual guidance. With regard to postoperative port-site herniation, there is no consensus on the minimum port-site size that necessitates closure; however, the need for closure of smaller port sites depends on both the size of the child and the type of trocar used.

Special considerations

Neuroblastoma

Neuroblastoma, the most common extracranial solid tumor of childhood, can occur anywhere within the sympathetic nervous system. Most often, however, these tumors originate within the adrenal medulla. The growth pattern of neuroblastoma is variable, ranging from sharply demarcated tumors to highly infiltrative lesions. The often infiltrative growth pattern of neuroblastoma has led most surgeons to excise these tumors via open resection, with the choice of a transabdominal vs retroperitoneal approach guided by tumor location and adjacent organ involvement. More recently, however, laparoscopy has been employed for the biopsy and resection of neuroblastomas.[12,28] Patients with tumors of limited size with clearly defined margins on preoperative imaging have undergone resection, whereas patients with advanced tumors have undergone laparoscopic biopsy prior to chemotherapy.[12,28] Laparoscopic adrenalectomy may be particularly suited for neuroblastomas identified by mass screening programs, which have been associated with a more favorable biology and clinical outcome than clinically diagnosed tumors.[29–33] Currently, the place for laparoscopy in the treatment of neuroblastoma continues to evolve, and the decision regarding treatment approach should be individualized.

Pheochromocytoma

Pheochromocytoma is a rare tumor of chromaffin cell origin that usually arises in the adrenal medulla. Approximately 10% of cases of pheochromocytoma occur in children, and the presentation of these tumors in the pediatric age group may be similar to that in adults.[34] Pheochromocytomas are characterized by catecholamine production; as such, the clinical manifestations of these tumors result from the physiologic effects of catecholamine excess.

Close cooperation of the pediatric urology, medicine, and anesthesiology teams is required in the management of patients with a pheochromocytoma. Patients are typically treated preoperatively with alpha-blockade (phenoxybenzamine) to control their blood pressure. Beta-blockers may be added to alpha-blockers to prevent arrhythmias, but beta-blockade administered without prior alpha-blockade may cause a significant increase in peripheral vascular resistance due to unopposed alpha activity.[15] In addition, many patients have decreased intravascular volume, and therefore intravenous fluids are aggressively administered in the perioperative period to expand plasma volume and minimize intraoperative and postoperative hypotension.[34]

The central tenet of adrenal surgery – removing the patient from the adrenal without manipulation of the gland – is essential during pheochromocytoma excision. Severe intraoperative hemodynamic instability from catecholamine release may occur if the adrenal is manipulated. An additional key principle of adrenalectomy for pheochromocytoma is early control and division of the main adrenal vein, in order to prevent the systemic release of catecholamines during dissection of the gland. Given the potential for blood pressure fluctuation which may occur after ligation of the adrenal vein, the anesthesiologist should be notified at the time of the vein's division, and should be prepared with intravenous fluids and vasopressors if needed.

As for the choice of surgical approach to pheochromocytomas, laparoscopic adrenalectomy has been reported as a safe and effective option in select patients.[35] The presence of multiple sites of disease and the suspicion of lymph node involvement are indications for open removal, which in such cases should be performed through a transabdominal approach.[15] For patients with bilateral adrenal lesions, partial adrenalectomy has been reported in an effort to preserve steroid synthesis and thereby avoid the need for lifetime glucocorticoid replacement therapy.[36,37] However, recurrence has been reported in up to 20–33% of patients undergoing partial adrenalectomy, and therefore close follow-up of these patients is recommended.[38]

Congenital adrenal hyperplasia

Hugh Hampton Young first reported adrenalectomy as a treatment for CAH in the 1930s.[1] With the development of synthetic adrenal steroids, however, the management of these patients has become almost exclusively medical (apart from genital reconstructive surgery). For most patients, the dosage of exogenous steroids needed to retard adrenal androgen production does not result in severe hypercortisolism with its associated sequela. However, in some patients, suppression of adrenocorticotropic hormone (ACTH) is difficult, requiring large doses of exogenous steroids, which may cause obesity, hirsutism, acne, and other cushingoid features. In women, hypercortisolism may in addition result in menstrual irregularities, significant bone loss, and infertility.[39]

Van Wyk et al revisited the concept of adrenalectomy as a treatment for CAH patients who were difficult to manage on medical therapy.[40] In a study of 18 patients who underwent bilateral adrenalectomy for treatment of CAH and were followed an average of 59 months, virtually all patients had a significant decrease in androgen excess.[41] A separate investigation reported two women with CAH who had been infertile and oligomenorrheic who then experienced successful pregnancies following bilateral adrenalectomy.[42] In addition, although the majority of studies on adrenalectomy as a treatment for CAH have involved patients with 21-hydroxylase deficiency, patients with 11β-hydroxylase deficiency, who are prone to develop hypertension as part of their disease process, have been treated with bilateral adrenalectomy as well, with a subsequent improvement in blood pressure.[40,43–46]

Lastly, whereas the aforementioned studies employed adrenalectomy as a treatment for CAH patients, the role of prophylactic adrenalectomy has been explored for patients with CAH as well.[39] Until longer-term data are available, however, prophylactic adrenalectomy is still considered experimental.

Key points

1. Adrenalectomy may be performed in the pediatric patient population using any of a variety of laparoscopic and open techniques; the optimal approach for a particular patient should be individualized

based on the size of the tumor, the pathology of the adrenal, the age and body habitus of the patient, and the experience of the surgeon.

2. Adrenalectomy should be performed with minimal manipulation of the gland itself; essentially, the patient should be removed from the adrenal.
3. During transperitoneal laparoscopic adrenalectomy, the lateral attachments of the gland are released last; these attachments are left intact to hold the adrenal in place for the remainder of the dissection.
4. Preoperative blood pressure control with alpha-blockade, perioperative intravenous hydration, and early ligation of the adrenal vein during surgical excision are keys to the management of adrenal pheochromocytoma.
5. Adrenalectomy may be a treatment alternative for patients with severe congenital adrenal hyperplasia who experience the sequela of iatrogenic hypercortisolism.

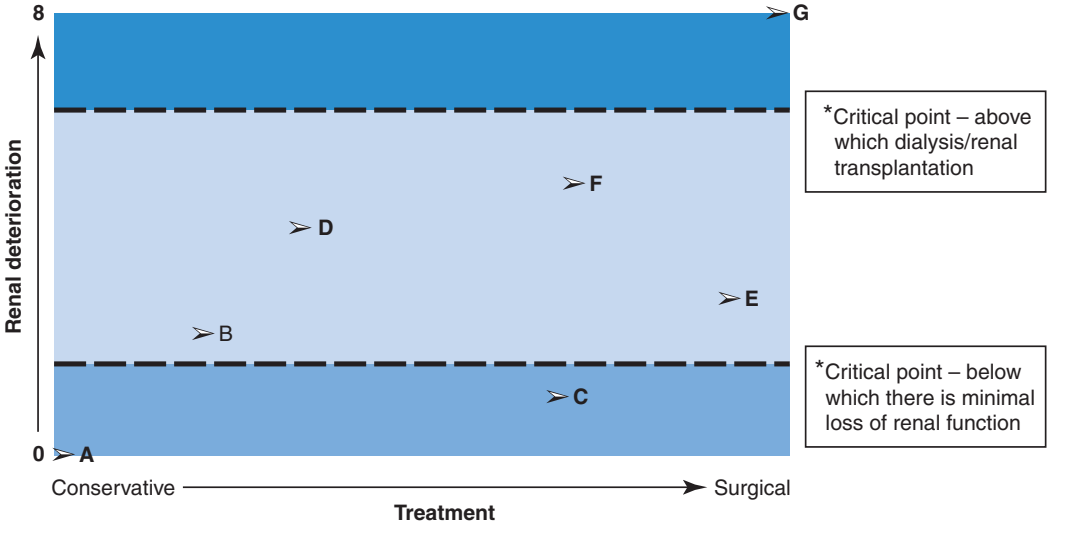
Section III

The Kidney

Basic science of the kidney



18

John C Thomas and John C Pope IV

Introduction

An attempt to define the term 'translational' compared it to deciphering a foreign language in that, 'getting the word right is relatively easy but getting the meaning of the word is much more difficult'.[1] The process of translating basic science research to improvements in clinical patient care has revolutionized the way medicine is practiced in the late 20th century and early 21st century. One example is in the area of renal transplantation. While the refinement of surgical technique has contributed to the overall success of the transplant, it is the monumental advances in immunobiology that have ultimately improved long-term outcome of the allograft. These translational efforts have led to the development of immunosuppressive drugs capable of preventing allograft rejection in the patient. Just as this type of research has contributed to the success of renal transplantation, pediatric urologists and nephrologists are faced with the issue of finding ways to prevent certain anomalies in their patients which ultimately lead to renal failure and the need for transplantation.

In order to address this issue, clinicians must first have a general understanding of normal and abnormal molecular renal development. Secondly, while urinary obstruction, untreated neurogenic bladders, and vesicoureteral reflux (VUR) are just a few known disease

Point A	Ideal goal – no loss of rental function with minimal treatment
Points B–F	Mild to severe loss of renal function despite varying degrees of treatment
Point G	Worst case – complete loss of renal function despite maximal treatment

Figure 18.1 Current technology generally allows clinicians to be within the pale blue and mid blue zone (points B–F). Despite maximal intervention, however, some patients progress to the dark blue zone (point G). Although point A may never be a possibility, the goals of current and future research on prognosticators of progressive renal injury should aim to keep all patients within the mid blue zone.

processes that can lead to progressive renal damage, current research is focusing on ways to detect at-risk individuals in whom early intervention is beneficial. Understanding the pathophysiology of nephropathy at the cellular level can provide potential markers that could possibly alert the caregiver to a particular problem before renal damage occurs (Figure 18.1). Unfortunately, despite our best efforts, some children will continue to develop renal failure, necessitating renal replacement therapy, and better alternatives such as xenotransplantation and tissue engineering of new organs need to be actively pursued.

This chapter briefly reviews the developmental biology of the kidney to highlight some of the more important regulatory factors involved in nephrogenesis. The pathophysiology of congenital obstructive nephropathy is used as an example to illustrate one congenital anomaly whose ultimate aberrant molecular events can lead to end-stage renal disease. More importantly, we focus on recent laboratory efforts which have elucidated numerous potential markers at the cellular level that play a role in the process of renal deterioration following insult to the developing kidney. Theoretic therapeutic options which act to inhibit or slow these damaging mechanisms as well as potential alternatives to present renal replacement therapy, namely tissue engineering and stem cell research, are also reviewed.

Molecular development of the kidney

As the embryology of the kidney is addressed in Chapter 19, this section focuses on the numerous molecular signals that result in normal renal development. Formation of the kidney is a culmination of reciprocal inductive signals that occur between the ureteral bud and metanephric blastema. The ureteral bud develops from the wolffian duct and the mesonephric mesenchyme arises from intermediate mesoderm located in the caudal portion of the nephrogenic cord. Once these structures interact, the nephrons develop from mesenchymal transformation and the collecting system is formed from ureteral bud outgrowth and subsequent branching.

Since 1993, almost 400 genes have been implicated in renal development and exist in the Kidney Development Database (http://golgi.ana.ed.ac.uk/kidhome.html).[2,3] Many of the major events in early renal development are controlled by highly conserved genes that regulate eye development in *Drosophila*.[4] The use of transgenic mice has also generated much data concerning nephrogenesis demonstrating that manipulation of a specific gene can result in phenotypes consistent with human congenital anomalies of the kidney and urinary tract (CAKUT). Mesenchymal–epithelial transition (MET) is a crucial process in the early renal development of the definitive metanephros. One of the most important regulators of this early step is a transcription factor known as *Pax-2*. Mice homozygous for the *Pax-2* null mutation lack ureters, kidneys, and genital tracts, whereas heterozygous mice often form hypoplastic kidneys.[5] Also, these animals lack expression of *c-ret*, an important tyrosine kinase receptor expressed on the tips of the ureteral bud.[5,6] The *c-ret* receptor binds glial-cell-line-derived neurotrophic factor (GDNF), which is secreted from the developing mesenchyme. Ureteral buds in mice lacking *c-ret* expression fail to branch, whereas loss of GDNF results in failure of ureteric bud outgrowth and secondary apoptosis of the metanephric mesenchyme. Both events lead to renal agenesis.[7,8] A similar phenotype is seen in mice with gene mutations encoding transcription factors that regulate *GDNF* expression, namely *Pax-2* and *Eya-1*.[9,10] *Eya-1* (*eyes absent*)-deficient mice lack expression of GDNF and exhibit absence of ureteric bud outgrowth and ensuing renal agenesis.

MET within the mesonephric mesenchyme occurs only following proper inductive signals from the invading ureteric bud. Once induction occurs, metanephric mesenchyme condenses at the tips of the branching bud to form mesenchymal aggregates. These aggregates epithelialize and undergo a morphogenetic sequence involving their transformation into nephrogenic tissue elements (termed renal vesicle, comma-shaped bodies, and S-shaped bodies) that fuse with adjacent ureteric bud branch tips and form primordial nephrons.[9] As condensation occurs, induced metanephric mesenchyme expresses *Wnt-4*, encoding a secreted glycoprotein, which promotes MET through an autocrine activation mechanism. Mice lacking *Wnt-4* fail to undergo epithelialization of metanephric mesenchyme and do not form nephrons.[11,12] Nephron maturation is also regulated by *Bmp-7*, a growth factor that is part of the transforming growth factor-β (TGF-β) superfamily of signaling molecules. *Bmp-7* appears to operate downstream of other factors such as *WT-1, Pax-2*, and *Wnt-4* and, like *Pax-2*, is expressed by both the mesenchyme and ureteral bud.[6] Homozygous mice with a mutation of *Bmp-7* have dysplastic kidneys that appear arrested in development. Whereas metanephric mesenchymal induction occurs in Bmp-7$^{-/-}$ mice, uninduced mesenchyme undergoes apoptosis,

Table 18.1 Genes involved in kidney development and the defect caused in mice lacking expression of the involved gene

Gene	Function	Homozygous loss in mice (–/–)[b]
WT-1[a]	Presence necessary for ureteral bud formation, precedes PAX2 and WNT-4 expression	Renal agenesis, absent ureteral bud formation
PAX-2[a]	Mesenchymal–epithelial conversion, expressed in ureteral bud, so probably has role	*PAX-2*$^{-/-}$ equals renal agenesis, absent ureteral bud formation; *PAX-2*$^{+/-}$ equals renal hypoplasia
WNT-4[a]	Morphogenesis of pretubular and tubular structures; mesenchymal–epithelial conversion	Small dysplastic kidneys
GDNF[a]	Ureteral bud formation; branching	Renal agenesis, absent ureteral bud formation
RET[a]	Receptor for GNDF–GDNFR-α complex, ureteral bud formation, and branching	Renal agenesis or tiny dysplastic kidneys
APC	Its protein product destabilizes β-catenin	In humans, mutations cause colon cancer
AT-1	Maturation of glomerular vessels, formation of renal pelvis	Absent renal pelves, immature glomeruli
AT-2	Mesenchymal cell apoptotic agent, has role in ureteral bud development	Congenital anomalies of kidneys and urinary tract
BCL-2	Prevents pre-epithelial, epithelial cell apoptosis	Renal agenesis, widespread apoptosis
BF-2	Present in mesenchymal cells that become stromal cells, persists in stromal cells, ureteral elongation, epithelial cell polarity	Short ureter, hypoplastic kidneys, incomplete rotation, renal fusion
BMP-4	Inhibits Wnt-11 activity, prevents ectopic ureteral bud formation, lengthens stalk of branches	*BMP-4*$^{+/-}$ equals congenital anomalies of kidneys and urinary tract
BMP-7	Prevents pre-epithelial cell apoptosis	Renal dysplasia
EMX-2	Ureteral bud branching, possible ureteral bud inducer of metanephric Wnt-4 expression, prevents pre-epithelial cell apoptosis	Renal agenesis, ureteral bud degeneration
EYA-1	May be inducer of GDNF expression and up-regulator of BCL-2	Renal agenesis, absent ureteral bud formation
FGF-2	Possible role in ureteral bud induction of mesenchymal–epithelial transformation	No published examples found
GDNFR-α	Auxillary receptor GDNF-α, ureteral bud formation; branching	Renal agenesis
IGF-II	Its protein product inhibits mesenchymal cell apoptosis	No published examples found
KAL-1	Specific role not known	In humans, mutation is associated with unilateral, bilateral renal agenesis
Id	Ureteral bud formation	Renal agenesis or dysplasia, absent ureteral bud formation or penetration
LIF-1	Activates STAT-3, possible requirement for epithelial tubulogenesis, may stimulate Wnt-4 expression	No published examples found
LIM-1	Not known but likely has role in mesenchymal–epithelial conversion	Some have bilateral renal agenesis
PDGF-β	Mesangial cell formation	Absent mesangial cells
PKD-1	Protein product is polycystin-1, tubule morphogenesis, participates in cell-to-cell, and cell-to-extracellular adhesion bonds	Autosomal dominant polycystic kidney disease
PKD-2	Protein product is polycystin-2, translocates polycystin-1 to cell membrane	No published examples found
RAR	Likely inducer of Hox activity	Renal agenesis or dysplasia
SHH	May have role in ureteral bud induction of metanephric development	Hypoplastic kidneys, defective branching
VHL	Strengthens destabilizing bonds of glycogen synthase kinase-3, adenosine polyposis coli with β-catenin	In humans, mutation causes von Hippel–Lindau disease
WNT-11	Ureteral bud branching	No defects

[a] These genes may be focused on but relative perceived importance of genes may change with time. Other genes are listed in alphabetical order. Some genes are not included in list and others have not yet been identified.
[b] Significance of each gene implied by the major defect that its absence causes.

Table 18.2 Genetic disorders for human congenital anomalies of the kidney and urinary tract (CAKUT)

Gene (chromosome)	Gene product/function	Clinical syndrome	Phenotypes/symptom
PAX-2 (10q24–25)	Transcription factor	Renal–coloboma syndrome	Renal hypoplasia, solitary kidney, vesicoureteric reflux, optic nerve colobomas hearing loss
KAL (Xp22.3)	Anosmin1 protein functioning in neuronal migration and axonal targeting	Kallmann syndrome	Hypogonadotropic hypogonadism, anosmia, pes cavus, mirror movements of the hands, high arched palate, carebellar ataxia, renal agenesis/aplasia. Potter sequence. duplex systems, vesicoureteric reflux, lack the vas deferens
EYA1 (8q13.3)	Organogenesis	Branchio-oto-renal syndrome	Branchial cysts or fistulae, external ear malformation, preauricular pits, hearing loss cataracts, ocular anterior segment anomalies, unilateral renal agenesis with contralateral hypodysplasia, bilateral hypodysplasia, bilateral renal agenasis, ureteropelvic junction obstruction, vesicoureteral reflux, bifid kidneys
AGTR2 (Xq22–23)	Angiotensin II receptor type 2		Common CAKUT
HNF-1β (17cen-q21.3)	Hepatocyte nuclear factor-1β, organogenesis	Maturity-onset diabetes of the young	Young-onset non-insulin-dependent diabetes mellitus, renal cysts, hypoplastic glomerulocystic kidney disease, cystic renal dysplasia, solitary kidney, Müllerian anomalies

Reproduced with permission from Nakanishi and Yoshikawa.[17]

suggesting that *Bmp-7* may function as a mesenchymal survival factor.[6]

Apoptosis plays a major role in the kidney achieving its characteristic reniform shape. As certain areas of the undifferentiated mesenchyme are destined to become crucial parts of the kidney, other cells undergo apoptosis. The renin–angiotensin system (RAS) plays a role in this process, mainly through the up-regulation of the angiotensin types 1 and 2 receptors (AT1 and AT2). The ligand for these receptors is angiotensin II, formed from the cleavage of angiotensin I by angiotensin-converting enzyme (ACE). Although AT1 receptors modulate renal vascular development and are found in more differentiated tissues of the kidney, AT2 receptors are expressed by undifferentiated mesenchyme (UMC).[13] Mice with a null mutation of the AT2 receptor display similar phenotypes to human CAKUT, including VUR, ureteropelvic junction obstruction, and duplicated collecting systems.[14,15] In-vitro and in-vivo studies show that angiotensin II promotes apoptosis of the UMC surrounding the developing urinary tract.[16] These studies suggest that mutations in AT2 can lead to untimely apoptosis of the UMC, potentially hindering not only the growth of the bud towards the mesenchyme but also the diffusion of signals between these structures. Thus, the bud may develop from an ectopic location from the wolffian duct and lead to VUR or renal hypo/dysplasia.[14] Numerous other factors and genes are involved in renal development; however, this is beyond the scope of this section of the chapter. Table 18.1 shows other important genes involved in nephrogenesis. Some of the aforementioned genes, as well as others, are involved in more common syndromes seen clinically, which are listed in Table 18.2.[17]

Congenital obstructive nephropathy

Congenital obstructive nephropathy is but one of many developmental aberrations that occur in the kidney/urinary tract which can lead to renal injury and, potentially, renal failure. Ideally, the embryologic process of urinary tract development could ultimately be controlled so that these anomalies do not occur. Short of accomplishing this feat, it is critical to know which patients are at risk for renal injury and/or failure. If these patients could be identified early, it would theoretically be possible to slow or prevent altogether this deterioration in renal function.

Currently, there is significant controversy regarding the management of individuals with significant hydronephrosis based on the fact that hydronephrosis is not synonymous with obstruction.[18] Both nonoperative and early operative approaches have been advocated for infants with severe unilateral hydronephrosis.[19,20] Based on a more thorough understanding of the pathophysiology of renal fibrosis, the potential use of 'biomarkers' may help to lessen this controversy. Biomarkers are defined as:[21]

> 'a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathological processes, or pharmacologic responses to a therapeutic intervention'.

Biomarkers for congenital obstructive nephropathy include anatomic details of the kidney gained through the use of imaging techniques, radionuclide scans to determine renal function, and microscopic analysis of biopsy specimens following obstruction.[21] The challenge faced by clinicians is learning how to use the information gained from these markers to direct appropriate care, such as timing of surgical intervention, medical treatment (i.e. administration of ACE inhibitors), etc.

Inconsistencies in the completion of nephrogenesis in various animal models have made it difficult to correlate postobstructive findings with those that occur in human obstructive nephropathy. Despite this shortcoming, animal models have contributed greatly to our understanding of fetal renal disease. These models consist of animals with spontaneous mutations or gene deletions (knockout), resulting in the desired phenotype as well as surgically induced models of renal obstruction.[22] There is a broad spectrum of severity of obstruction in the human, and occult renal damage at the cellular level probably occurs prior to the development of hydronephrosis. Perhaps the most accurate model to demonstrate this is the neonatal rat, as only 10% of its nephrons are formed at birth while the rest develop during the first week of life.[23] Thornhill et al subjected the neonatal rat to partial unilateral ureteral obstruction (UUO).[24] In this study, a 70–75% reduction in ureteral lumen resulted in a 60% reduction in renal growth and the number of glomeruli decreased by 50%. Also, tubular atrophy and interstitial fibrosis correlated with tubular apoptosis and developed prior to renal pelvic dilation. Finally, persistent moderate partial UUO led to a marked decrease in ipsilateral glomerular filtration rate (GFR) and proteinuria before impairment of renal growth.[24] These findings carry extremely important clinical implications, as currently no diagnostic test exists that allows one to reliably predict whether a hydronephrotic kidney is at risk for progressive renal injury at the cellular level.

Following the tireless efforts of numerous investigators, we now have a better understanding of normal renal development along with the different mechanisms of renal damage following obstruction. Normal nephrogenesis includes increasing the number of nephrons and maturation of the renal vasculature, glomeruli, tubules, and interstitium. This complex process involves the RAS and a balance between cellular proliferation and programmed cell death (apoptosis).[25,26] Significant obstruction can lead to impaired renal growth resulting from tubular dilation and apoptosis, tubular atrophy, inflammatory infiltration of the interstitium, and unchecked accumulation of the extracellular matrix, all culminating in renal fibrosis and glomerulosclerosis.[21,27,28]

The following section will outline important mediators in fibrotic renal disease by briefly discussing their actions at the cellular level. Since other conditions seen clinically in pediatric urology can also result in renal fibrosis, these mediators can potentially be used as prognostic indicators of renal damage and be universally applied to multiple disease processes. Finally, once the role of these markers is understood, potential therapeutic options based on the activation or inhibition of their actions will be discussed.

Transforming growth factor-β_1

TGF-β_1 is a regulatory cytokine that is up-regulated in response to tissue injury and can act synergistically with other growth factors to either inhibit or stimulate extracellular matrix (ECM) deposition by recruiting fibroblasts.[29] Overaccumulation of ECM proteins, including fibronectin, collagen, and proteoglycans, as well as

blocking matrix degradation by stimulating the action of protease inhibitors, results in fibrosis.[29–31] Tissue and urinary TGF-β_1 has been shown to be increased in both animal and human models following urinary tract obstruction.[32,33] TGF-β exists as three isoforms (β_1, β_2, and β_3) all capable of inducing fibrogenic effects on the obstructed kidney.[34] The main isoform is TGF-β_1 and, using immunohistochemistry in kidneys subjected to UUO, this cytokine has been localized to the renal tubules in the cortex and outer medulla as well as to infiltrating macrophages in the interstitium.[35]

The complexity of TGF-β signaling is beyond the scope of this chapter, but, initially, TGF-β binds the type II serine/threonine kinase receptor, which then recruits and phosphorylates the type I receptor, resulting in its activation. This receptor complex can then activate multiple signaling pathways, including RhoA, p38 mitogen-activated protein kinase (MAPK), phosphatidylinositol 3-kinase (PI3K), and the Smad pathway.[36–38] Downstream phosphorylation of Smad-2 results in the nuclear translocation of Smads 2, 3, and 4 protein complexes.[39,40] Smad 3 has been implicated in the fibrotic process through the activation of collagen promoters, down-regulation of matrix-degrading enzymes, and up-regulation of matrix metalloproteinase (MMP) inhibitors.[40] TGF-β_1 also drives epithelial–mesenchymal transition (EMT), which is characterized by tubular epithelial cell migration into the interstitium, where epithelial cells are transformed into mesenchymal, myofibroblast-type cells. Renal tubular cells express fibroblast-specific protein-1 (FSP-1), which can be induced by TGF-β_1 released by infiltrating macrophages or fibroblasts during renal injury. This activation allows certain epithelial cells to acquire mesenchymal migratory capacity and escape into the interstitium, where they facilitate deposition of interstitial ECM.[41–43]

TGF-β_1 and its signaling pathways are major contributors to renal fibrosis following renal injury, and any of the numerous factors involved have the potential to serve as important biomarkers for subclinical renal injury following obstruction. If patients at risk for progressive renal fibrosis can be identified, then hopefully intervention can take place to slow, stop, or potentially reverse the fibrotic process.

The renin–angiotensin system

In addition to TGF-β_1, the RAS has also been implicated in the pathophysiology of renal fibrosis following obstruction. Along with regulation of renal growth, investigators have shown that the RAS plays a major role in the early response of a neonatal kidney following obstruction and that reduced growth was secondary to decreased cellular proliferation and increased apoptosis.[44,45] Consistent with this early activation of the RAS in the neonatal kidney, there is a prompt and marked increase in ipsilateral renin mRNA following unilateral UUO with contralateral suppression of renin in the neonatal rat as compared to adult rats. Persistence of an immature microvascular renin distribution, presence of α-smooth muscle actin (α-SMA) in the peritubular capillaries, and decreased total DNA content in the obstructed neonatal kidney all confirm the deleterious effects of obstruction in the developing kidney.[46,47] Angiotensin II directly increases the production of TGF-β and can induce fibrosis via a TGF-β-dependent or -independent mechanism through direct activation of plasminogen activator-1 (PAI-1).[48–54] PAI-1 promotes fibrosis by preventing the breakdown of plasminogen to plasmin (Figure 18.2).[50]

In-vitro studies of oxidative stress on rat proximal tubular cells illustrate the role of angiotensin II in the promotion of cellular apoptosis. This is primarily mediated via the induction of TGF-β and generation of reactive oxygen species (ROS).[55] The RAS promotes normal renal development but in cases of obstructive uropathy can promote fibrosis and accentuate renal injury through a variety of mechanisms. Consequently, therapies directed at inhibition of the RAS carry much promise in attenuating renal damage secondary to urinary tract obstruction.

Apoptosis

Following chronic ureteral obstruction, tubular and interstitial cells undergo programmed cell death, or apoptosis, which leads to renal tissue loss.[56,57] Once the inductive signal for apoptosis occurs, this leads to the recruitment and activation of cytosolic enzymes called caspases (cysteinyl aspartate-specific proteinases). Using a mouse model of UUO, investigators showed a progressive increase in the activation of these caspases, namely caspase-3, as compared with sham-operated animals.[57] Apoptosis of both tubular and interstitial cells paralleled this increase in caspase expression.

Many signals, including growth factors, cytokines, ROS, and angiotensin II, are able to initiate apoptosis. A neutralizing antibody to TGF-β ameliorated tubular apoptosis following UUO in the rat, whereas administration of enalapril, an ACE inhibitor, pro-

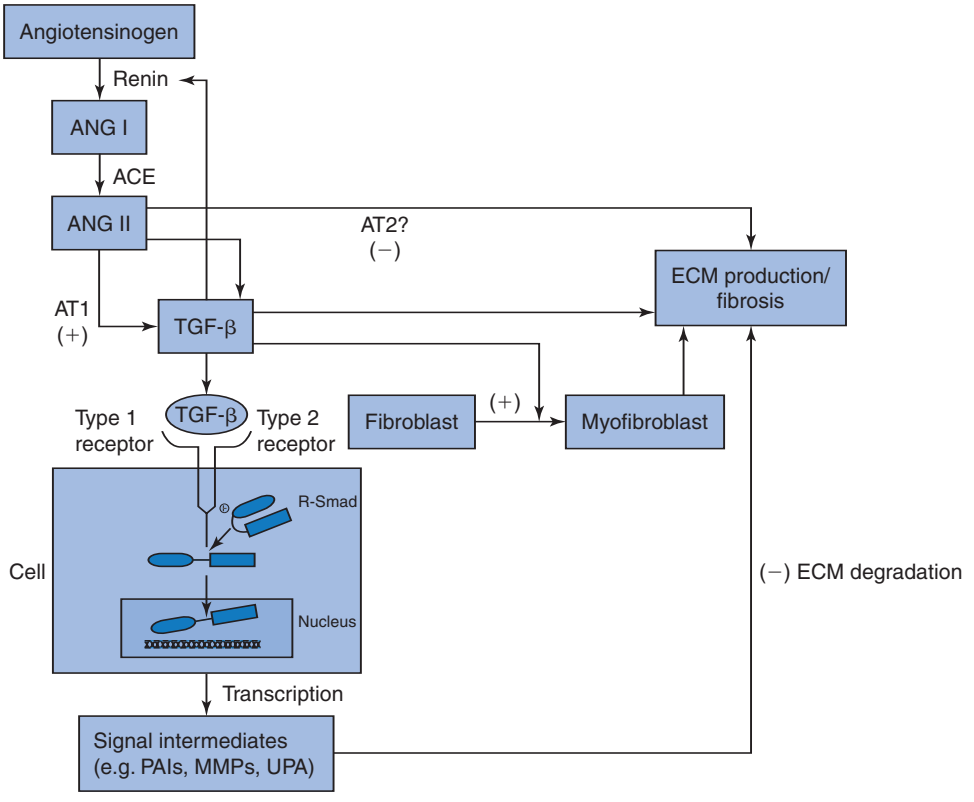

Figure 18.2 Summary of the roles played by the renin–angiotensin system, TGF-β, and TGF-β-downstream signal mediators in tissue fibrosis. ANG 1, ANG II, angiotensin I and II; ATI, AT2, angiotensin type 1 and 2 receptors; R-Smad, receptor-activated Smad; ECM, extracellular matrix; PAIs, plasminogen activator inhibitors; MMPs, matrix metalloproteinases; UPAs, urokinase-type plasminogen activators.

vided partial protection against tubular cell apoptosis.[58] Nuclear factor-κB (NF-κB) is an inducible transcription factor that upon translocation to the nucleus can induce the transcription of various genes, including bcl-2 family members, angiotensinogen, and proinflammatory mediators such as tumor necrosis factor-α (TNF-α).[59] Angiotensin II and TNF-α can stimulate further activation of NF-κB, reinforcing a positive feedback loop.[31] Increased vascular resistance following UUO causes transient ischemia and increased release of angiotensin II. Once obstruction is relieved, ischemia/reperfusion injury may result secondary to increased release of ROS such as hydrogen peroxide (H_2O_2). Following UUO in mice lacking catalase, an enzyme capable of neutralizing H_2O_2, there was in increase in tubular epithelial cell apoptosis and interstitial fibrosis as compared to wild-type mice.[60,61]

Finally, recent evidence has linked nitric oxide (NO) as a possible protector against apoptosis. NO is produced by inducible nitric oxide synthase (iNOS), which is spontaneously expressed in the kidney. Using knockout mice lacking iNOS, investigators showed increased tubular cell apoptosis.[62] From a clinical standpoint, iNOS activity has also been shown to be elevated in children with ureteropelvic junction (UPJ) obstruction, presumably induced by inflammatory cytokines such as TNF-α and monocyte chemoattractant protein-1 (MCP-1); the latter was also found in the urine of children with UPJ obstruction.[63,64] Further studies are needed, however, to evaluate NO as a prognostic indicator of recoverability of renal function following urinary obstruction.[62]

The above processes were meant to highlight different signals and processes involved in progressive renal damage following obstruction. By no means is this an exhaustive description, as many other mechanisms have been implicated. Although presented separately, it is important to remember that these processes occur simultaneously and that induction of one process may be dependent on another. This may have a therapeutic benefit, as inhibiting one signal or process can have the advantageous and additive effect of attenuating another.

Treatment options

Renal fibrosis and atrophy secondary to various diseases are complex processes that have become more understandable in the last 10 years through the work of numerous investigators. Defining and detecting this process earlier may allow us to manipulate and possibly prevent renal damage by inhibiting a specific growth factor, cytokine, or blocking an entire pathway by interfering with upstream or downstream mediators.[65,66] As previously discussed, TGF-β plays a major role in renal fibrosis following obstruction. Potential treatment options include TGF-β neutralizing antibodies, antisense oligonucleotides, and blockade with a naturally occurring proteoglycan called decorin, all of which have limited ECM accumulation in vivo and in vitro.[58,67,68] Targeting the RAS with ACE inhibition and AT1 blockade results in impaired fibroblast proliferation, decreased myofibroblastic differentiation, and lowering of both TGF-β levels and NF-κB isotype activation. Of note, ACE inhibition also attenuated monocyte/macrophage infiltration.[69,70] NF-κB is responsible for the up-regulation of various cytokines, inflammatory mediators, and intercellular adhesion molecules such as ICAM–1. Inhibition of NF-κB in rat kidneys subjected to UUO using an activation inhibitor called dehydroxymethylepoxyquinomicin (DHMEQ) showed less interstitial fibrosis and volume as compared to obstructed controls.[71] Smad 3-deficient mice undergoing UUO showed decreased scar formation, less α-SMA staining in the interstitial fibroblasts, and decreased deposition of both collagen I and III.[72] Using a nephrotoxic nephritis model in the rat, treatment with a pan-caspase inhibitor decreased apoptosis, tubulointerstitial inflammation, and mRNA levels of collagen I, III, and IV.[73] Finally, because the role of MCP-1 has been firmly established as a profibrotic modulator, blocking its receptor CCR2 also decreased fibrosis following UUO in a mouse model.[74]

Epidermal growth factor (EGF) is also an important peptide whose manipulation has potential therapeutic ramifications following UUO.[75] EGF is produced by the ascending loop of Henle and distal convoluted tubule and modulates epithelial cell growth and metabolism, and plays a role in renal repair following injury.[64,76] EGF is decreased in the urine of children with congenital UPJ obstruction, whereas levels of MCP–1 are increased.[64] Following 5 days of UUO in the neonatal rat, the number of nephrons was decreased despite administration of exogenous EGF. However, tubular vimentin was decreased by one-third and, more importantly, tubular atrophy was reduced by 58% at 1 month following relief of UUO, an effect not seen in control animals.[77] Thus, administration of exogenous EGF could potentially slow the deleterious effects of obstruction on the maturing kidney.

Advances in renal replacement therapy

Despite our best efforts, some children will still progress to renal failure secondary to various causes, including obstructive uropathy. Renal transplantation continues to be limited by an organ donation shortage as well as the effects of organ rejection and the need for multiple organ transplants. Numerous scientific advances in the fields of tissue engineering and stem cell research have given these patients hope that options other than organ transplantation may be available in their lifetimes. Unfortunately, kidney reconstitution is difficult because in addition to excreting urine, there are many metabolic and endocrine functions of the kidney that maintain body homeostasis.[78] In contrast to pluripotent embryonic stem cells (EC), organ-specific stem cells have the potential to produce lineage-restricted cell types.[79] In-vitro experiments have shown that differentiated cell types in the adult kidney arise from two embryologic sources, namely the ureteric bud and metanephric mesenchyme.[80] Hammerman stated:[81]

> 'in order for glomerular filtration, reabsorption, and secretion of fluid and electrolytes to take place in a manner that will sustain life, the nephrons must be integrated in three dimensions with one another and with a collecting system and that vascularization must occur in a unique organ-specific manner from endothelial precursors that may originate from both inside and outside the developing renal anlage'.

Initial studies confirmed that implantation of developing nephrons into the cortex of newborn mice resulted in differentiation and growth of the donor nephrons. Incorporation of these nephrons, however, into the host collecting system was not seen.[82,83] Studies have also shown that human fetal kidney tissue grafted under the renal capsule of immunodeficient rodents evoked a lower immune response compared with grafting adult renal tissue.[84] In addition, the fetal kidney has the potential not only to incorporate growing vessels from the developing abdominal

aorta, but also to attract its own vasculature in situ, which is important in terms of maintaining viability during transplantation.[85] Transplantation of a developing embryonic rat kidney into the omentum of an immunocompetent rat following unilateral nephrectomy resulted in increased renal growth, maturation of tubules and glomeruli, and incorporation of host blood supply from the superior mesenteric artery.[86] More importantly, survival in an anephric rat was prolonged to 7 days by this transplanted kidney.[87,88] Based on the above examples, there has clearly been a tremendous effort by investigators into research on organ replacement and regeneration. Ongoing research is needed in these areas as they may one day represent viable alternatives to renal transplantation in humans.

Finally, in an attempt to find a more physiologic, yet still extracorporeal alternative to dialysis, Humes et al developed an artificial kidney that maintained the metabolic, endocrinologic, and filtration demands in acutely uremic dogs.[88] This kidney consists of a synthetic hemofiltration cartridge with a renal tubule cell-assist device (RAD) in which human renal tubule cells have been grown to confluence along the inner surface of the hollow fibers.[88,89] A recent phase I/II Food and Drug Administration (FDA)-approved trial using this device in intensive care unit (ICU) patients with acute renal failure showed that this experimental therapy could be delivered safely for up to 24 hours.[89]

Conclusion

Prevention of nephropathy will continue to be a major focus of pediatric urology clinicians and researchers. The goal of this chapter was to identify and discuss general areas of importance where research of multiple types can make a clinical impact. However, the information given is only a snapshot of selected research contributions and in no way represents the vast and continuous efforts by other investigators in the field. The potential of molecular biomarkers to serve as prognostic indicators of cellular damage is at the forefront of renal research. As technology diversifies, new research opportunities will also continue to materialize. These may include the use of genetically engineered animal models, targeted gene therapies, or improved surgical procedures with miniaturized instrumentation or the use of robotic assistance.

Although currently we cannot prevent renal failure, research in the laboratory has given us valuable insight into normal and abnormal renal development, mechanisms underlying renal damage, and new ways to administer renal replacement therapy. Open communication between clinicians and researchers as well as the increased training of physician–scientists will help fuel future research possibilities. In the end, what is learned in the laboratory will continue to be translated into a better quality of life for our patients.

Renal vasculature and kidney 19

Steven E Lerman, Irene M McAleer, and George W Kaplan

Renal vasculature

The primitive vasculature is forming during the first 3 gestational weeks. Angioblasts form from mesenchymal cells that separate from the primary trophoblast at the same time as other mesoderm is forming. These angioblasts appear in the body stalk and form isolated vascular spaces or blood islands which become lined with endothelium.[1] Growth and union of these isolated spaces form plexi, which eventually unite to form a system of closed vessels. Mesenchyme laid down around the endothelium forms the intima, media, and adventitia of the vessels. Once this system of closed vessels is in place, any new vessels that arise do so as outgrowths of existing vessels. Definitive vessels arise by selection, enlargement, and differentiation. The selection of resulting channels is by virtue of inherited patterns and hemodynamic factors. Vasculogenesis factors, such as vascular endothelial growth factor (VEGF) and erythropoietin (EPO), have been extensively studied in various animal models with correlative studies ongoing in human embryogenesis and fetal placental angiogenesis.[2–4] It is during this period that paired dorsal aortae arise. In addition, paired postcardinal veins form to return blood to the heart from the caudal end of the body via a common cardinal vein. These postcardinal veins develop as vessels of the mesonephroi and run dorsal to them. The previously paired dorsal aortae fuse at the level of the fourth thoracic vertebra to the fourth lumbar vertebra to form a single descending aorta in the 4th week. Lateral branches of the dorsal aorta appear during the 5th week. These irregularly segmented vessels supply structures arising from the nephrotome region, specifically the mesonephros, gonads, metanephros, and suprarenal glands. The number of lateral branches is reduced with involution of the mesonephros; these lateral branches ultimately become the inferior phrenic, adrenal, renal, and gonadal arteries.

During the 6th week, the formation of the inferior vena cava starts (Figure 19.1). Subcardinal veins develop ventromedial to the mesonephroi and connect with each other and with the postcardinal veins. The posterior cardinal veins, which supply the mesonephric kidneys, will ultimately disappear when the mesonephroi involute with the exception of remnants as the root of the azygos vein and the common iliac veins.[1] Supracardinal veins develop dorsomedial to the postcardinal veins and replace them. This process progresses during the 6th to the 8th week of gestation, when formation of the inferior vena cava is complete. Connections between the subcardinal veins persist as a common stem uniting the left renal vein, the left adrenal vein, and the left gonadal vein to the vena cava. The right subcardinal vein forms the inferior vena cava at the level of the renal veins and cephalad; it is for this reason that the right adrenal vein and the right gonadal vein drain directly into the inferior vena cava. The right supracardinal vein persists as the inferior vena cava below the renal veins, whereas the left supracardinal vein disappears entirely.

Although there are many normal variations in renal arterial supply, most tend to be variations of the arrangement of five segmental arteries: posterior, upper anterior, middle anterior, apical, and inferior polar.[6] During renal ascent from the pelvis, the developing kidneys receive their blood supply from the vessels that are closest to them. With normal ascent stopping where the kidneys meet the adrenal (suprarenal) glands, the blood supply to the kidneys initially comes from the common iliacs but, ultimately, will arise from branches off of the aorta. The earlier blood vessels will involute and disappear unless there is incomplete ascent.[1] Accessory renal arteries will arise if some of the precursors do not involute; most arise from the aorta either superiorly or inferiorly. Accessory arteries are present in about 25% of adult kidneys and are more common than accessory veins. Obstruction of the proximal ureter can occur if an inferiorly placed accessory artery is present and if that artery crosses over the ureter (Figure 19.2).

Persistence of the right subcardinal vein as the infe-

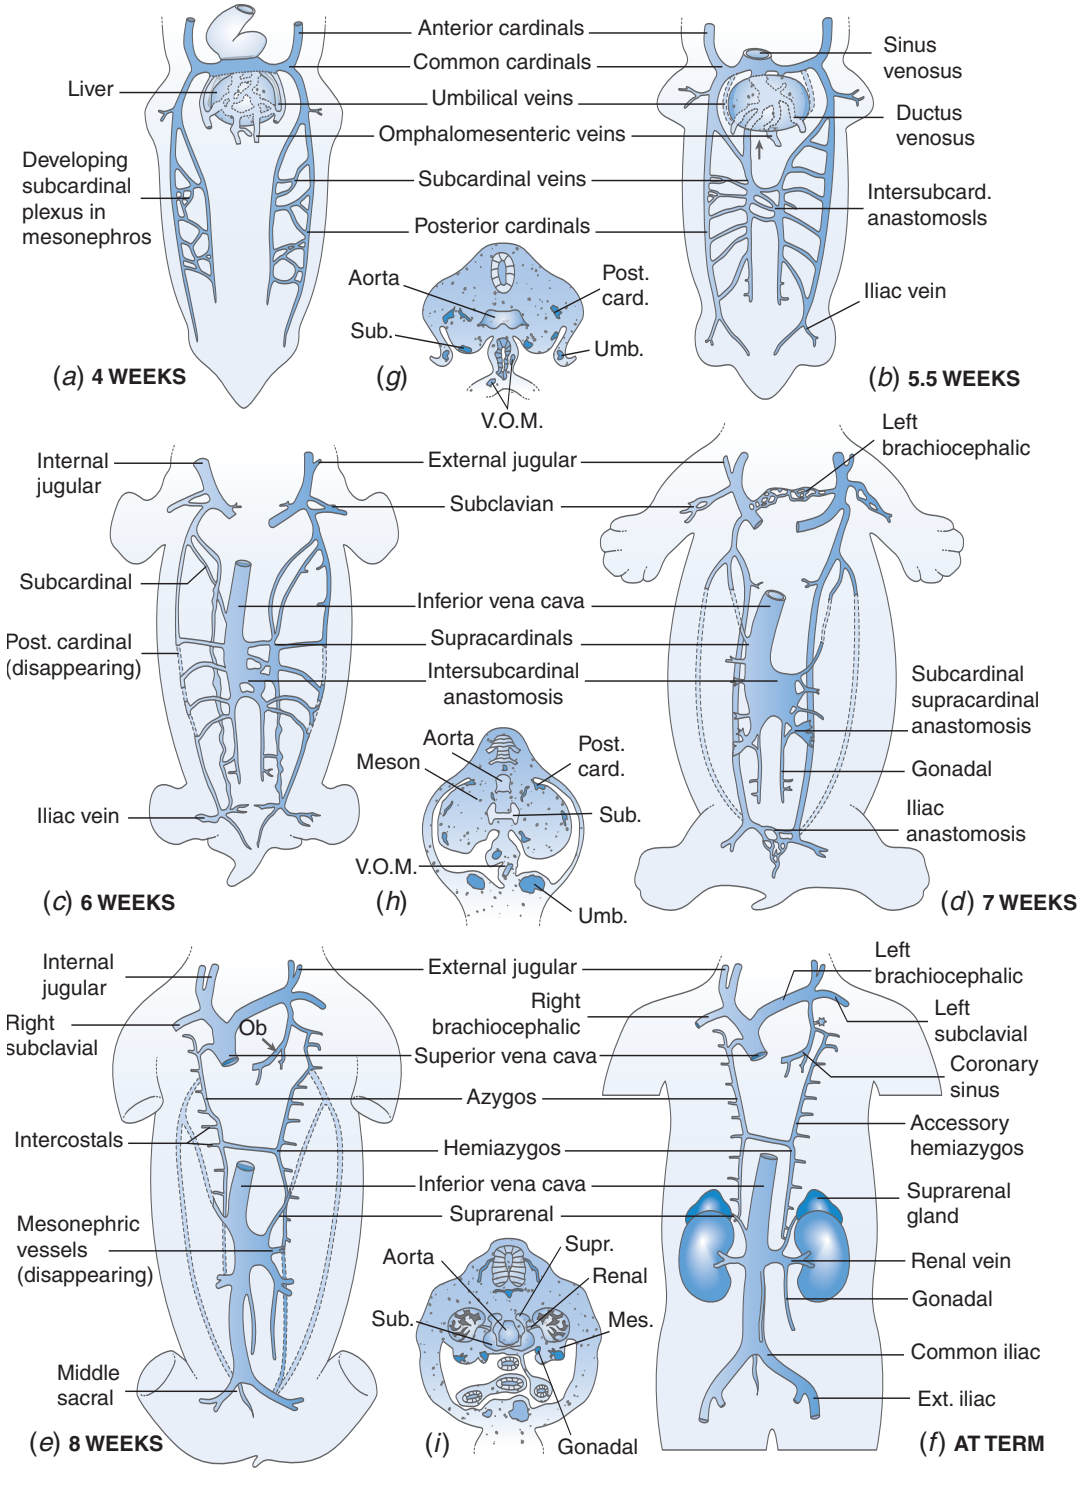

Figure 19.1 Development of the superior and inferior vena cava: (*a–f*) anterior views; (*g–h*) cross-sectional views. V.O.M., omphalomesenteric veins. (From Patten.[5])

rior vena cava rather than the supracardinal vein will result in a retrocaval ureter. All reported cases of retrocaval ureter have been right-sided except when situs inversus is present.[7]

Retroiliac ureter is a rare anomaly that may result if the iliac artery should form from a ventral root of the umbilical artery rather than a segmental branch of the aorta as it normally does in the 4th week.[8]

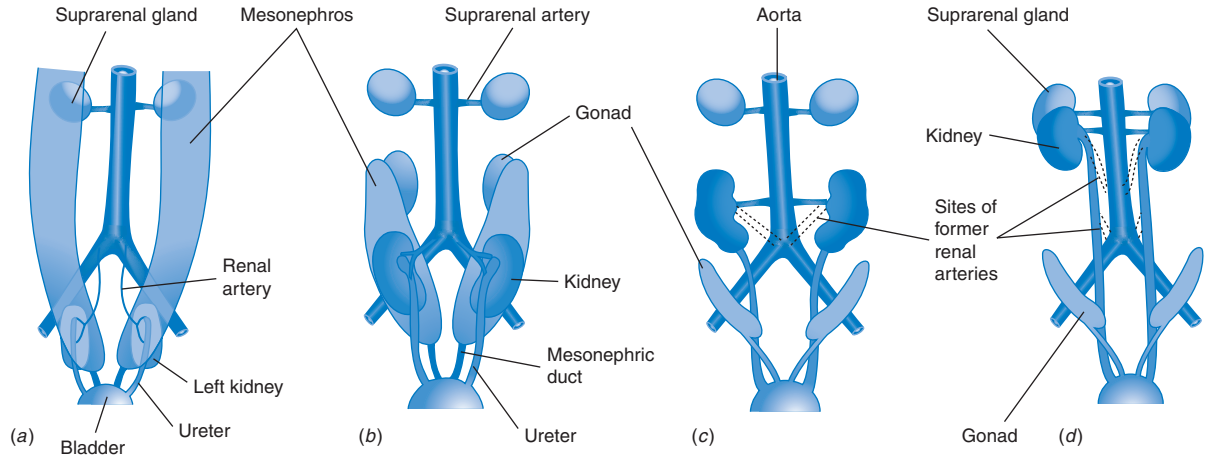

Figure 19.2 Ascent of the kidneys. (*a–d*) Diagrammatic ventral views of the abdominopelvic region of embryos and fetuses (6th–9th weeks) showing medial rotation and 'ascent' of the kidneys from the pelvis to the abdomen. (*a* and *b*) Observe also the size regression of the mesonephroi. (*c* and *d*) Note that as the kidneys 'ascend,' they are supplied by arteries at successively higher levels and that the hilum of the kidney (where the vessels and nerves enter) is eventually directed anteromedially. (Reproduced with permission from Moore and Persaud.[1])

Kidney and ureter

The urogenital system develops from the intermediate mesoderm arising from the dorsal body wall but will ultimately be ventrally located as a result of embryonic folding. This mesoderm arising on either side of the descending aorta will form the urogenital ridge. The urinary system starts developing before the genital system.[1]

There are three sets of kidneys that develop in mammalian embryogenesis. The first to form, during the first 21 days of development, are the pronephroi. These non-functioning units arise in the cervical and thoracic region of the embryo (Figure 19.3). The pronephros does not function in mammals but is analogous to the kidney in primitive fish. Seven pairs of tubules arise as dorsolateral sprouts from segmentally arranged nephrotomes (specialized areas of mesoderm). As the last tubule appears, the earliest is degenerating. The distal ends of these tubules bend dorsally, canalize, and unite one with another into a longitudinal collecting duct. This collecting duct eventually reaches the cloaca and communicates with it. The pronephric ducts persist and are necessary for the next interim kidney development. If the pronephros or its duct do not develop, the mesonephros will not form.

Late in the 4th gestational week, the mesonephros arises from nephrotomes caudal to the pronephros; these nephrotomes are unsegmented, unlike the pronephric nephrotomes. The mesonephric mesoderm separates into a longitudinal bar termed the nephrogenic cord. Within this cord, the mesenchyme forms into tubules. One end of the tubule becomes associated with a knot of blood vessels, while the other opens into the original pronephric duct, now called the mesonephric duct. With this process, the nephrogenic cord becomes subdivided into spherical masses of cells that appear progressively from its cranial end to its caudal end. These masses will hollow and send out solid extensions that unite with the mesonephric duct. These solid extensions canalize and, with linear growth, bend into an S-shape. A knot of blood vessels (the glomerulus) indents the free end of the tubule, which now becomes Bowman's capsule (Figure 19.4). Bowman's capsule and the glomerulus together make up the mesonephric corpuscle. Lateral branches of the aorta feed the glomerulus, while the postcardinal veins drain these tubules by sinusoids. The mesonephric tubules between the mesonephric duct and the glomerulus elongate and form a secretory segment and a collecting segment. As the tubules enlarge, the nephrogenic cord bulges into the coelom, forming a urogenital ridge on each side of the dorsal mesentery extending roughly from the diaphragm to the cloaca (Figure 19.5).

The pronephric tubules have completely degenerated by the 4th week but the pronephric duct persists as the mesonephric (wolffian) duct. The mesonephros begins to reach its stage of maximal development by the 28th day, with about 30 tubules in each mesonephros. The cranial tubules of the mesonephros degenerate while others are forming caudally. Unlike the pronephroi, the mesonephroi are well developed

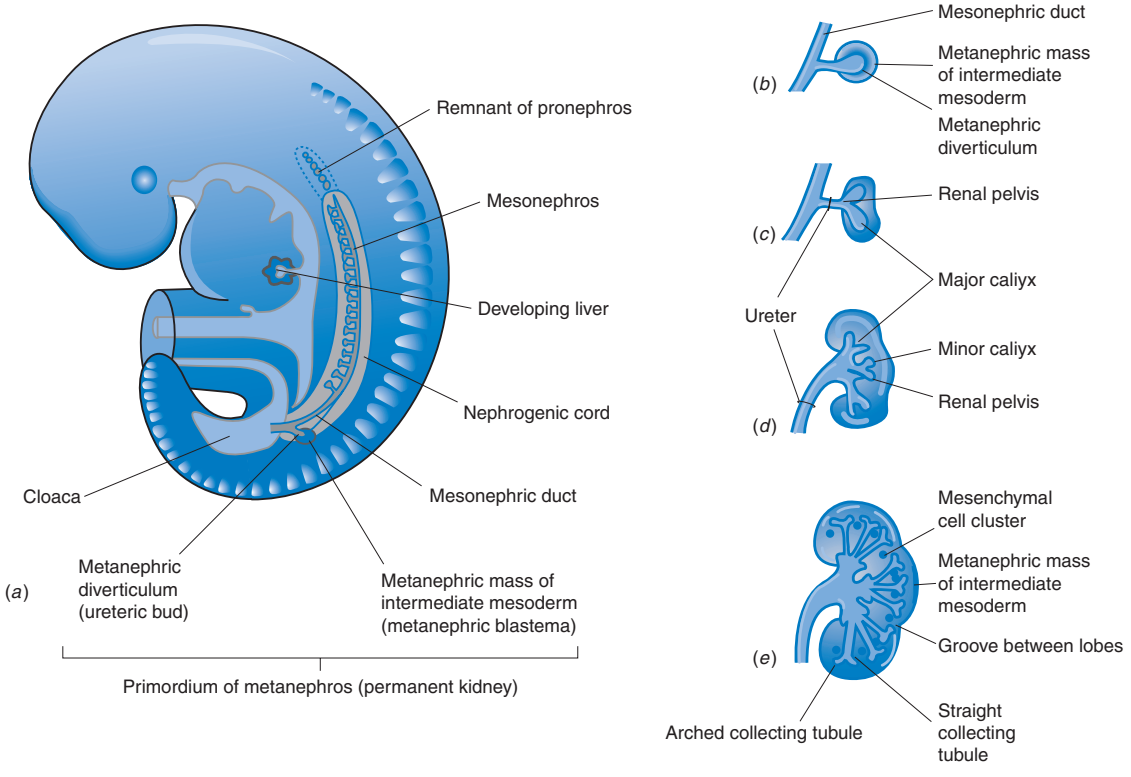

Figure 19.3 Development of the permanent kidney. (*a*) A lateral view of a 5-week embryo, showing the primordium of the metanephros. (*b–e*) Successive stages in the development of the metanephric diverticulum or ureteric bud (5th–8th weeks). Observe the development of the ureter, renal pelvis, calices, and collecting tubules. and will function as interim kidneys for about 4 weeks. The glomeruli in animals studied (rabbits, cats, and pigs) can excrete ferrocyanide at this stage, while the tubules can secrete phenol red. At the caudal end of the nephrogenic cord, at the level of the sacral vertebrae deep in the pelvis, the metanephros soon appears as a metanephrogenic mass (nephric blastema).

The mesonephric duct makes a sharp bend before it enters the cloaca (see Figure 19.3). The ureteric bud, which will become the ureter, renal pelvis, calices, and collecting ducts, arises from the dorsal medial aspect of this bend. It hollows, grows dorsad, and then cephalad. It pushes into the metanephrogenic mass, composed of intermediate mesoderm, and separates from the nephrogenic cord; the interaction between the ureteric bud and the metanephric mass begins to induce nephrogenesis. The proximal end of the ureteric bud elongates to form the ureter, while the distal end, that portion pushing into the metanephrogenic mass, becomes the renal pelvis. The metanephrogenic mass surrounds the renal pelvis like a cap.

In the 5th week, early development of the permanent kidney is occurring, having been induced by the key union of the ureteric bud with the metanephrogenic mass. The kidney is initially oriented in an anteroposterior direction with the ureter entering the hilum of the kidney anteriorly (see Figure 19.2). With elongation of the ureter and straightening of the body, the kidney 'ascends' from its pelvic position to its eventual normal site, just below the suprarenal or adrenal glands; during the 5th week, however, the kidney is still caudal to the umbilical arteries. Late in the 5th week, the kidney begins to turn 90° on its vertical axis so that, ultimately, its dorsal border becomes its lateral border.

By the 6th week, the kidney has ascended sufficiently so that it lies cephalad to the umbilical artery. The renal pelvis flattens and divides into two major calices. By the 7th week, the kidney comes into contact with the suprarenal body, shortens and widens; by the 8th week, the center of the kidney has reached its permanent level opposite the second lumbar vertebra. The caudal pole is above the iliac vessels and the cranial pole below the suprarenal gland (see Figure 19.2).

From the 6th to the 20th week, the major calices progressively subdivide through 12 generations. The second, third, and fourth generations enlarge and fuse to form approximately nine minor calices. The fifth generation of branches (about 25 in number) form papillary ducts, emptying into the minor calices. The sixth to 12th generations of branches form the collecting ducts in the renal medulla and project into the renal cortex. All the tubules draining into a minor calyx constitute a renal pyramid, the base of which adjoins the renal cortex, while its apex (papilla) projects into a calyx. The calices, pelvis, and ureter differentiate into transitional epithelium and become invested with smooth muscle and connective tissue by specialization of the surrounding mesenchyme during the 8th week.

The cap of metanephrogenic tissue that covers the ureteral bud has two layers: an external layer, which forms the renal capsule and connective tissue, and an inner layer, which forms the nephrons. The inner layer divides as the renal pelvis branches, so that a

small cap of metanephrogenic tissue covers each subdivision through all 12 generations. As the renal cortex organizes, the region over each pyramid is demarcated from the next pyramid, so that as many as 20 lobes are formed. This lobation disappears progressively in infancy and early childhood but may be readily apparent on routine ultrasonographic examination as fetal lobulations, especially in infants.

During the 7th week, the inner layer of the metanephrogenic tissue begins to condense into spherical masses about the ends of the branches of the ureteral bud. These masses hang down into the angles between the branches. As the cortex thickens, new spheres form. The spheres change into vesicles and elongate, producing an S-shaped secretory tubule, which unites with a collecting tubule. The blind end of the secretory tubule becomes the Bowman's capsule, while the mid-portion elongates and twists. An afferent arteriole grows in, the glomerulus differentiates, and an efferent arteriole grows out. The combination of the developing elongating metanephric vesicles later to be the metanephric tubules and the glomerulus, including Bowman's capsule, will become the future nephron. Nephrogenesis starts in third-generation ureteral branches in the mid-portion of the kidney and in fifth-generation branches at the poles. Nephrogenesis, or formation of nephrons, continues through the 36th week of gestation and then ceases. Although the number of nephrons does not increase with age, the size of the nephron increases throughout somatic growth.

The fetal kidney is capable of secretion by the 10th week of gestation, and urine is produced. The bladder fills and urine is voided into the amniotic sac. The amniotic fluid is imbibed by the fetus and is an important factor in pulmonary maturation. A mature fetus can swallow several hundred milliliters a day, which is then absorbed by the fetal intestines. Fetal waste products are transferred through the placenta into the maternal circulation for disposal.

Scientific research has been quite extensive in human and animal models concerning the molecular control and triggering of embryonic development. Previously, normal renal development was thought to hinge on the metanephric diverticulum or ureteral bud making contact with the metanephric mass. Presently, the theory of reciprocal induction of the kidney through important interactions between the ureteral bud and the metanephric cap explains that the nephrons will not develop without the ureteral bud meeting the metanephric mass and, of equal importance, the branching of the ureteral bud will not occur without the metanephric mass stimulating the ureteral bud to branch. In other words, embryonic renal development is thought to be due to signals from adjacent tissues, and coordination of normal organ development depends on appropriate interactions between constituent parts at the appropriate time for that development.[1]

Molecular and gene studies in laboratory animals suggest that *WT1* (a Wilms' tumor suppressor gene) is necessary in the metanephric mass to induce the ureteral bud to form through presumed regulation of production of GDNF (glial-cell-line-derived neurotrophic factor). Once this GDNF is present, it stimulates branching of the ureteral bud through receptors (c-ret) first located on the mesonephric duct and then found on the ureteral bud. Other molecules regulate nephron induction such as transforming growth factor (TGF-β_2), bone morphogenetic protein 7 (BMP7), and nephron maintenance and differentiation such as fibroblast growth factor-2 (FGF-2), and leukemia inhibitory factor (LIF). Still other molecules, including PAX-2, BCL-2, ANG II (angiotensin II), and HGF (hepatocyte growth factor), are thought to regulate apoptosis of the developing kidney tubules and nephrons.[1,10–12] Animal studies (transgenic mice) suggest that sonic hedgehog (Shh) may promote mesenchymal cell proliferation and differentiation of the developing smooth muscle around the ureteral bud and, thus, if there is abnormal signaling from Shh, the ureteral smooth muscle may not develop normally and hydroureter and/or hydronephrosis may ensue. If there is not enough Shh activity, the ureteral smooth muscle development may be aberrant and facilitate dysplastic or obstructive changes in the developing kidney.[13]

CAKUT, or congenital anomalies of the kidney and urinary tract, was coined by several urologists and nephrologists who noted that there were divergent thoughts in the two communities about the causes of abnormal development of the kidneys and urinary tract and the research within the two fields can be complementary rather than divergent. This combined system approach concerning the effects that the developing kidney has on the developing ureteral system and the reciprocal effects of the ureter on the kidney may explain the various malformations that occur due to aberrant reciprocal induction in the urinary system.[14]

Multiple anomalies result from disordered embryogenesis of the ureter or kidney. Some are known to be familial, at least in some instances (e.g. ureteral duplications, vesicoureteral reflux), whereas others are

frequently associated with chromosomal abnormalities (e.g. horseshoe kidney and Turner's syndrome). Most, however, seem sporadic in incidence.

If the pronephrosis fails to develop, the mesonephros will not develop; the result is renal and ureteral agenesis. Unilateral renal agenesis occurs in approximately 1 in 1000 newborns. Males predominate in occurrence, as does a proclivity to the absent kidney being on the left. Additionally, in the male, the ipsilateral genital ducts do not form. Hence, there is a high association of renal agenesis in patients with congenital absence of the vas deferens.[15] A similar situation would result if the mesonephric duct failed; however, if the mesonephric duct developed but the mesonephros did not, the kidney would be absent, while the genital ducts, and perhaps a blind-ending ureter, could result. If both kidneys fail to develop, oligohydramnios (due to a lack of fetal urine) produces the deformation characteristic of Potter's syndrome (characteristic facies with low set ears, hypertelorism, and flattened nose, as well as limb deformities due to relative absence of amniotic fluid) and interferes with pulmonary maturation. Occurrence of bilateral renal agenesis is approximately 1 in 3000 live births and is incompatible with postnatal life.

Failure of renal ascent results in simple pelvic ectopia. Further ascent but failure of rotation is seen clinically as malrotation or incomplete rotation either maintaining the normal embryonic anteriorly placed renal pelvis or over-rotation with either a laterally or a posteriorly placed renal hilum. Many of these kidneys are also ectopically located. If the two metanephrogenic masses come into contact in the pelvis they could fuse and form a pancake (lump) kidney. Fusion slightly later, usually in the lower pole of the developing kidneys, might result in horseshoe kidney. The ascent of the horseshoe kidney is arrested by the inferior mesenteric artery. Horseshoe kidneys occur in about 1 in 500 people. These kidneys have a 2–8 times higher risk for Wilms' tumor development than in the general population. The embryogenesis of crossed ectopia is harder to explain, but it may result from lateral bending and rotation of the tail of the embryo, thereby altering the course of ascent. In this way both ureteral buds might penetrate a single metanephrogenic mass.[16] Supernumerary kidney formation is relatively rare. Formation of this anomaly is due to the division of the ipsilateral ureteral bud (Figure 19.6).

Cystic renal disease can occur with inherited conditions or through disruptions in normal development.

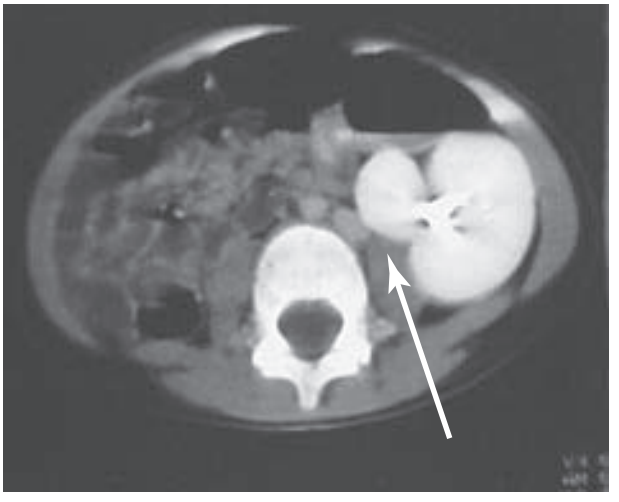

Figure 19.6 Computed tomographic image of supernumerary kidney on left (arrow) and absent right kidney.

Autosomal recessive polycystic kidney disease (ARPKD) is a recessively inherited autosomal disorder that is reported to occur in 1 out of 6000–14 000 pregnancies. These kidneys are quite large and may replace most of the retroperitoneum. The cysts are due to enlargement of the collecting ducts; associated liver disorders with periportal hepatic fibrosis is also seen with this disorder. Those infants who do not survive infancy expire due to renal or pulmonary failure. Imaging of ARPKD kidneys with ultrasonography or postnatal computed tomography (CT) is characterized by very large kidneys with a streaking sunburst pattern (Figure 19.7).

Autosomal dominant polycystic kidney disease (ADPKD), which is more common than the recessive form, is characterized by cysts forming through abnormal branching of the collecting ducts as well as cysts forming in other portions of the tubules.

Multicystic dysplastic kidney disease (MCKD) has been said to result from early ureteral obstruction,[17] or may result from disordered induction of the metanephrogenic mass by a faulty ureteral bud.[18] Complete involution of the cystic components of the multicystic kidney also accounts for some cases of renal agenesis. MCKD is the most common form of cystic disease, with a frequency of 1 in 3000 pregnancies. In this disorder, there is no recognizable renal tissue present on gross examination, but there may be some dysplastic renal tissue interspersed with the cystic elements. Bilateral MCKD is incompatible with life, but approximately 75% of cases are found with unilateral MCKD involvement. These kidneys can be

found with antenatal ultrasonography (Figure 19.8). Cysts in this case are thought to be due to dilations of the tubules, especially the loops of Henle.

Embryonic development theory suggests that normal nephrogenesis is dependent upon the ureteral bud meeting the center of the metanephrogenic mass, so that nephrogenesis is induced by the ureter.[19,20] Should they not meet at all, a blind-ending ureter would result. However, should they meet in an abnormal (degenerating) part of the metanephrogenic mass, renal dysplasia would be anticipated.[19,21] Study of the molecular basis of abnormal renal development with molecular and gene factors and markers is ongoing.[14]

Pathogenesis of dysplastic kidneys has been studied extensively using animal models of urinary tract obstruction at various times in fetal gestation. Kitagawa et al developed a model for MCKD by ligating

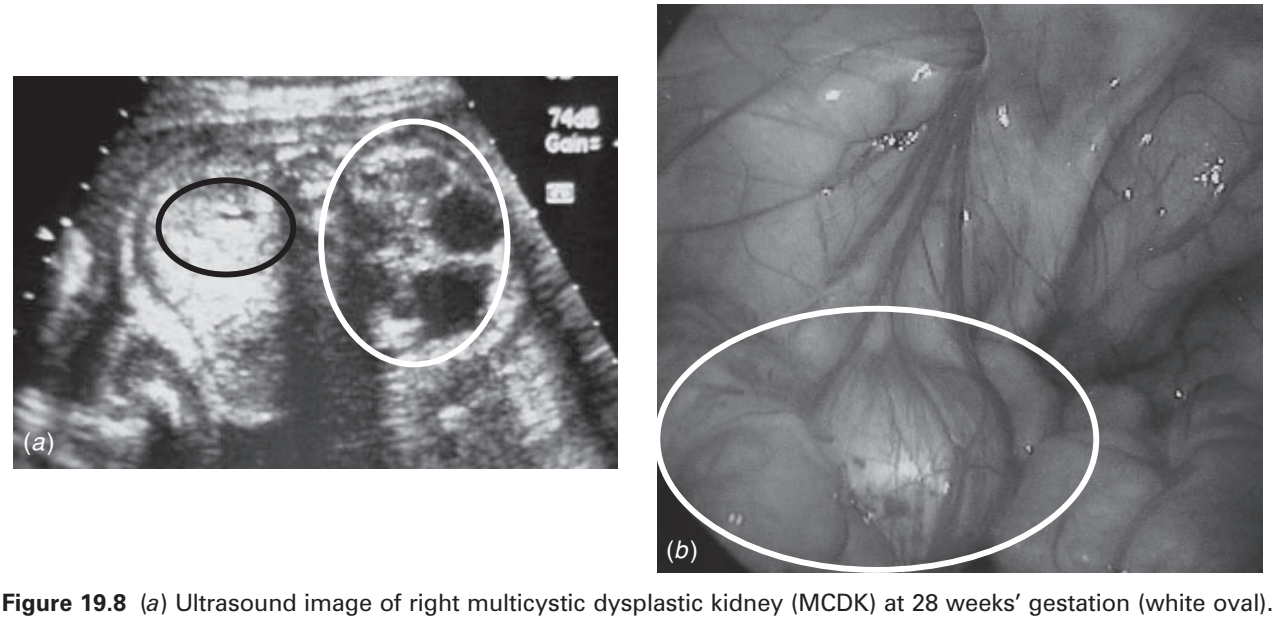

Figure 19.8 (*a*) Ultrasound image of right multicystic dysplastic kidney (MCDK) at 28 weeks' gestation (white oval). Normal left kidney (black oval). (*b*) Laparoscopic picture of left pelvic MCDK of a different patient (white oval).

fetal lamb urethras at various times during gestation. They found a dysplastic kidney similar pathologically to a multicystic kidney when the urethras were ligated at 60 days' gestation, well after the glomeruli started producing urine.[22] Recent human fetal tissue studies using 3D histologic analysis theorize that there may be other other processes involved in the development of renal dysplasia arising from urinary tract obstruction. These studies suggest that there may be two different types of dysplasia: MCKD models and obstructive renal disease models rather than abnormalities due to faulty induction of the metanephric mass by the ureteral bud. Shibata and Nagata used human fetal renal tissue and felt that the cystic dysplasia occurred earlier in gestation in MCKD, since cystic areas appeared to decrease with increased gestational age while interstitial dysplastic tissue increased with later gestational age. They found that cysts were more peripherally located with obstructive renal disease and the rest of the kidney architecture was generally normal. They theorize that these cysts developed later in gestation because the effect of obstruction of the urinary tract occurs lower and must affect the urethra, bladder, ureter, or renal pelvis before it affects the developing nephrons. In MCKDs, the obstruction is associated with pyelocaliceal obstruction, which is much higher in the urinary tract and, therefore, will have an earlier dysplastic affect on the kidney.[23,24]

Renal anomalies

20

Michael L Ritchey and Susan John

Embryology

Renal anomalies may be the result of an arrest in development or a malformation. A complete understanding of the embryologic development of the genitourinary tract is a prerequisite for the evaluation of a child with a suspected anomaly. Anomalies of the urogenital tract are among the most common of all organ systems. Using real-time ultrasonography as a screening test in healthy infants, Steinhart et al found that 3.2% of infants had an abnormality of the genitourinary tract and half of these required surgical intervention.[1] Shieh et al noted a 0.5% incidence of renal abnormalities using portable ultrasound screening of school-age children.[2]

The development of the urinary tract can be divided into two segments, the nephric system and the vesicourethral system.[3] There are three stages in the formation of the nephric system. The two intermediate stages are the pronephros, which completely disappears, and the mesonephros. Although the mesonephros undergoes degeneration, its duct persists and extends caudally to communicate with the anterior cloaca. Vestigial remnants of the mesonephric tubules occur in both sexes and are associated with the reproductive tract. Early in the 4th–5th weeks, the ureteral bud begins to develop from the distal end of the mesonephric duct near its junction with the cloaca. The cranial end of the ureter then ascends to meet the nephrogenic cord of the intermediate mesoderm. This begins to develop into the metanephros and continues its cephalad migration. The cranial end of the ureteral bud begins a series of branchings to form the renal pelvis, the calices, and a portion of the collecting ducts.[4] This branching is associated with the simultaneous differentiation of the metanephrogenic cap, which becomes arranged around the branching collecting ducts, and ascends. The ascent of the kidneys occurs in part due to true migration and also secondary to differential somatic growth of the lumbar portion of the body. They reach their final level by the end of the 8th week of fetal life (Figure 20.1). The kidney also undergoes axial rotation medially of 90° during the 7th and 8th weeks before it assumes its final position. During ascent, each kidney receives its blood supply from the neighboring vessels. Initially, this is from the middle sacral artery, then the common iliac and inferior mesenteric arteries, and finally the aorta.

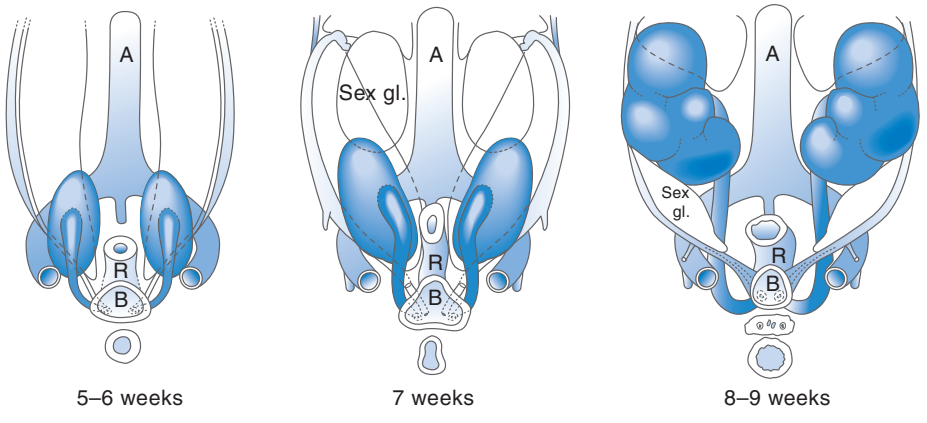

Figure 20.1 Ascent and rotation of kidneys during fetal life. The normal rotation of the kidney from facing forward to facing medially is shown. A, aorta; R, rectum; B, bladder; Sex gl, sex gland. (From Campbell.[5])

Anomalies in number

Supernumerary kidney

A supernumerary kidney is an uncommon anomaly, with no more than 100 cases reported in the literature.[6–9] The embryologic basis shares some similarities with that found in ureteral duplication. There are either two ureteral buds arising from the mesonephric duct, leading to double ureters, or a branching of the ureteral bud, that results in a bifid collecting system. The two ureteral buds then either join two separate metanephroi or a splitting of the nephrogenic blastema occurs. This later develops into twin metanephroi after induction by the two ureteral buds. It is not necessary for the two ureteral buds to be widely divergent.[8]

The supernumerary kidney is caudal to the ipsilateral kidney in 60% of cases. A supernumerary kidney associated with complete ureteral duplication is more likely to be in a cranial location. There is generally one extra kidney, but as many as five separate renal masses have been reported. This anomaly occurs more frequently on the left side. The ureter of the anomalous kidney joins the ipsilateral ureter about as commonly as it enters the bladder separately, but only rarely is the ureter ectopic. The extra kidney has its own renal capsule and blood supply. The supernumerary kidney is often smaller and one-third exhibit other pathologic changes (e.g. hydronephrosis, pyelonephritis). Renal function is frequently decreased in the smaller hypoplastic unit.

Most cases are diagnosed after the third decade of life. Presenting complaints are usually related to urinary obstruction or infection and include pain, fever, or an abdominal mass.[10] However, many patients remain asymptomatic throughout life and 20% of reported cases were discovered at autopsy.[11] The diagnosis can be readily established with current imaging modalities; nuclear renal scintigraphy will confirm the presence of functioning renal tissue.[12]

Unilateral renal agenesis

Renal agenesis results from a failure of induction of the metanephric blastema by the ureteral bud. This could result from agenesis of the ureteral bud or Wolffian duct, failure of the bud to reach the blastema, absence or abnormality of the metanephric blastema, or failure of the ureteral bud to invade the metanephric blastema.[13] It is unclear whether there is a genetic predisposition or if it is related to other prenatal factors. Parikh et al found diabetes and black maternal race were associated with an increased incidence of renal agenesis, but it is probably multifactorial, with both environmental and genetic factors playing a role.[14] A familial tendency has been reported, supporting the latter.[15] The reported incidence of this condition varies between series of patients collected from either clinical or autopsy data. Doroshow and Abeshouse estimated that unilateral renal agenesis (URA) is found in 1 of every 1100 autopsies.[16] A similar incidence has been noted in school-age children undergoing ultrasound screening.[2] The clinical incidence on imaging studies is 1 in 1500, suggesting that most cases are diagnosed during life.[17] Currently, most renal anomalies seen by pediatric urologists are detected prenatally and URA is no exception, but fetal ultrasound studies have detected renal agenesis with a much lower frequency.[18,19] Many patients previously reported with URA probably had prior involution of multicystic or dysplastic kidneys. This has been documented to occur prenatally,[20] and rapid involution of multicystic and dysplastic renal units has also been shown to occur early in postnatal life.[21,22] Hiraoaka et al have suggested that aplasia is the predominant cause of congenital solitary kidneys.[23] There is a slight male predominance, and the condition occurs more frequently on the left side. This male predominance may reflect the earlier differentiation of the Wolffian duct that takes place close to the time of ureteral bud formation. The ureteral bud is more likely to be influenced by abnormalities of the Wolffian duct than that of the Müllerian duct, which occurs later.

Associated anomalies

The ipsilateral ureter is absent in 50–87% of cases and only partially developed in the remainder.[24] On cystoscopy, a hemitrigone will be present in patients with complete ureteral agenesis. Anomalies of the contralateral kidney are common, with reflux the most frequent finding, followed by ureterovesical and ureteropelvic junction obstruction.[25–27] Limakeng and Retik reported an increased incidence of contralateral abnormality if a hypoplastic ureter was associated with the absent kidney.[28] The ipsilateral adrenal was found to be absent on autopsy in 8% of patients with URA.[24] One report noted ipsilateral adrenal agenesis in two of seven patients with URA examined with abdominal ultrasonography.[29]

The most commonly associated abnormalities are those of the female genitalia. The incidence ranges from 20 to 60%.[16,30] Likewise, patients with known

genital anomalies have an increased incidence of renal anomalies.[31] Complete absence or hypoplasia of the vagina, the Mayer–Rokitansky–Küster–Hauser syndrome, is frequently associated with agenesis of the kidney.[32–34] Most of the genital anomalies in female patients with URA are asymptomatic, but such anomalies often assume greater clinical importance, leading to earlier evaluation and diagnosis of the absent kidney. The most common problems involve the uterus and vagina. There is often a unicornuate or bicornuate uterus (Figure 20.2), and the ipsilateral horn and fallopian tube may be rudimentary or absent.[35] A duplex uterus is attributable to a developmental anomaly of the urogenital septum, resulting in incomplete midline fusion of the Müllerian ducts and a longitudinal vaginal septum. The development of the Müllerian duct appears to be inhibited by the defective Wolffian duct if the defect occurs early in development.[36] Defects of the ureteral bud that occur after Müllerian duct fusion will affect only ureteral and renal development.[37] Obstruction of the lower genital tract can occur, leading to hydrocolpos or hematocolpos. Patients present with a pelvic mass or pain and fail to menstruate at puberty.[38] Patients with complete Müllerian arrest will require vaginal construction to achieve adequate sexual function but will be infertile.

The vas deferens, seminal vesicle, and ejaculatory duct are absent in 50% of males with URA.[39] Conversely, in those patients presenting with an absent vas, the reported incidence of renal agenesis varies greatly. Donahue and Fauver found an absent kidney in 22/26 (85%) patients with an absent vas deferens.[40] Goldstein and Schlossberg used computed tomography (CT) to evaluate 26 men with absence of the vas deferens.[41] Unilateral renal agenesis was noted in only four men, in all of whom the seminal vesicle was absent. Schlegel et al found an 11% incidence of renal agenesis in infertile men with unilateral agenesis of the vas.[42] Of interest, men with both agenesis of the vas and renal anomalies rarely had *CFTR* gene defects. Cysts of the seminal vesicle associated with URA or dysgenesis and an ectopic ureter have also been reported.[43] The ipsilateral testis is usually present.[24] Cystic dysplasia of the rete testis is associated with a high incidence of URA.[44]

Figure 20.2 Bicornuate uterus seen on hysterosalpingogram with filling of both fallopian tubes. The vagina was normal in this patient with an absent right kidney.

Approximately 25–40% of patients with URA have anomalies of other organ systems. Most frequently affected are cardiovascular (30%), gastrointestinal (25%), and musculoskeletal (14%).[45] Unilateral renal agenesis is associated with several syndromes, including Turner's, Poland's,[46] Goldenhar's,[47] VACTERL association,[48] and Klippel–Feil syndromes.[49]

Diagnosis

Absence of the kidney may be suspected on a plain film of the abdomen if the gas pattern of the splenic or hepatic flexure of the colon is displaced into the renal fossa.[50] This non-specific finding is also found after the kidney has been surgically removed. The diagnosis is confirmed by an absent kidney and contralateral compensatory hypertrophy on excretory urography. Sonography will also reveal an empty renal fossa, but the hypertrophied adrenal gland can be mistaken for a small kidney.[51] In these cases, the adrenal gland loses its 'Y' and 'V' configuration and becomes flatter and more elliptical in shape. This flattened adrenal gland has been described as the 'lying down' sign and can also be noted in renal ectopy.[52] Radionuclide imaging should be performed in all children with the diagnosis of a solitary kidney, as it can identify small, poorly functioning kidneys missed by other imaging studies. Renography will also reveal kidneys that are ectopically located.[53] As noted above, cystography is recommended in all children with URA due to the increased risk of vesicoureteral reflux (VUR). Ultrasound and magnetic resonance imaging (MRI) are useful for examining the internal genital structures in females with a diagnosis of renal agenesis. In general, the uterus and cervix can be visualized in both infants and older girls. Renal sonography has been recommended for screening of parents and siblings of children born with renal agenesis. Roodhooft et al reported a 9% incidence of asymptomatic renal malformations in family members, with URA the most common finding.[54]

Prognosis

Hypertrophy of the solitary kidney occurs as an adaptive compensatory response. This hypertrophy has been shown to occur in utero.[55] There are both experimental and clinical studies suggesting that hyperfiltration of remnant nephrons may have an adverse effect on renal function, depending on the number of nephrons remaining.[56] There are reports of focal glomerulosclerosis, the renal lesion that develops in hyperfiltration, occurring in humans with URA.[57–59] Some studies have noted an increased rate of hypertension, proteinuria, and mild renal insufficiency.[60,61] However, others have noted normal renal reserve in patients with URA.[62] Although the risk of significant renal disease is low, we advise our patients to have annual measurement of blood pressure and urinalysis to assess for proteinuria.

Bilateral renal agenesis

The incidence of bilateral renal agenesis (Potter's syndrome) is 1 in 4000 births, with a slight male predominance (male : female ratio of 2.5 : 1).[63] A familial tendency has been reported, and the risk of recurrence in subsequent pregnancies is 2–5%.[64] These infants have a characteristic facies (Figure 20.3) that is found in conditions in which there is an absence of intrauterine renal function. The most constant finding is a prominent epicanthal fold that extends onto the cheek. The skin of these infants is very loose, particularly over the hands. Oligohydramnios during pregnancy is profound, except in rare instances. This causes intrauterine compression of the fetus, which results in other characteristic external features, including bowed legs and clubbed feet. The most significant sequelae of oligohydramnios is pulmonary hypoplasia. This is the result of compression of the thoracic cage, preventing lung expansion, lack of pulmonary fluid stenting the airways, or absence of renal factors, such as proline production.[65]

Approximately 40% of such infants are stillborn, and the remainder rapidly succumb to respiratory failure associated with the pulmonary hypoplasia unless aggressively treated. This poor prognosis has led to the recommendation of termination of the pregnancy if the diagnosis is made early in gestation.

The ultrasound criteria for diagnosis of a fetus with bilateral renal agenesis are the presence of severe oligohydramnios or anhydramnios occurring after 14–16 weeks' gestation, failure to visualize both kidneys, and non-visualization of the bladder. Prior to 16 weeks gestation, relatively little of the amniotic volume is due to fetal urine. Because fetal imaging is very difficult in severe oligohydramnios, non-visualization of the urinary bladder is a more reliable indication of fetal renal non-function than the inability to identify the fetal kidneys.[66] Caution must be used in accepting the antenatal diagnosis of bilateral renal agenesis, because false-positive diagnoses have been made. Color Doppler sonography is recommended to establish the presence or absence of renal arteries.[67] MRI may facilitate assessment of the fetus with possible bilateral renal agenesis.[68]

Figure 20.3 Potter's facies. (Courtesy of Dr Catherine Poole, University of Miami, Florida.)

The ureter is absent in the majority of cases and only partially developed in the remaining individuals.[24] The bladder is either absent or severely hypoplastic as a result of the absence of urine flow. The adrenal glands are rarely absent or malpositioned, but are flat.[52] External genital development is usually normal except when bilateral renal agenesis occurs in a sirenomelic monster. Testicular absence has been reported in up to 10%, but the vasa are usually present.[52] The presence of the vasa suggests that this anomaly is not due to failure of the Wolffian duct to

develop. The organs most often abnormal in the female are derived from the Müllerian structures. In both sexes, there is an increased incidence of spina bifida and gastrointestinal malformations, imperforate anus in particular. A regional disturbance affecting the posterior portion of the cloaca and the adjacent mesonephros and Müllerian ducts is probably responsible for these associations.[63]

Anomalies of rotation

Abnormal rotation, or malrotation, is most commonly associated with an ectopic or fused kidney, but may also occur in kidneys that undergo complete ascent. In the normal adult kidney, the renal pelvis is oriented medially and the calices point laterally. The fetal kidneys undergo a 90° rotation during the 6th–8th weeks of embryonic development to achieve normal orientation (see Figure 20.1). The rotation of the fetal kidney has been proposed to be the result of differential growth, with more tubules being formed on the ventrolateral side than on the dorsomedial side.[69] This theory does not explain all of the abnormalities of rotation. Weyrauch suggested that the ureteral bud makes more lateral contact with the renal blastema. This may explain an anomalous initial position of the kidney, but does not explain normal renal rotation. Campbell reported only 17 cases of renal malrotation among 32 834 autopsies on adults.[70] Smith and Orkin found an incidence of 1 in 390 and stated that malrotation accounts for 10% of upper urinary tract anomalies.[71] The true incidence of this type of anomaly is probably understated because in many patients there are no clinical manifestations.

The different types of malrotation are depicted in Figure 20.4. The most common is an incomplete rotation, or non-rotation (Figure 20.5). The renal pelvis is anterior or between the fetal anterior and normal medial position in the adult. Other major types of anomalous rotation are reverse rotation and hyper-rotation (excessive rotation) in which the kidney faces laterally, but these are rare (Figure 20.6).[72] In reverse rotation, the renal pelvis rotates laterally and the renal vessels cross the kidney anteriorly to reach the hilum (Figure 20.7). In excessive rotation, the kidney rotates more than 180° but less than 360°. The pelvis faces laterally, but the renal vessels are carried posteriorly to the kidney. Less severe hyper-rotation may leave the renal pelvis in a dorsal position.[3]

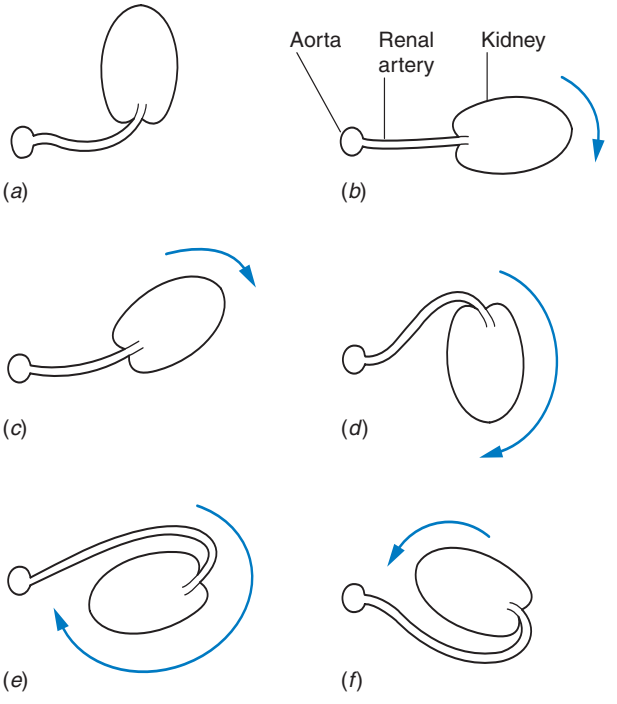

Figure 20.4 Rotation of the kidney during its ascent from the pelvis. The left kidney (with its renal artery) and the aorta are viewed in transverse section to show normal and abnormal rotation during its ascent to the adult site. (*a*) Primitive embryonic position, hilus faces ventrad (anterior). (*b*) Normal adult position, hilus faces mediad. (*c*) Incomplete rotation. (*d*) Hyper-rotation, hilus faces dorsad (posterior). (*e*) Hyper-rotation, hilus faces laterad. (*f*) Reverse rotation, hilus faces laterad. (From Parrott et al.[3])

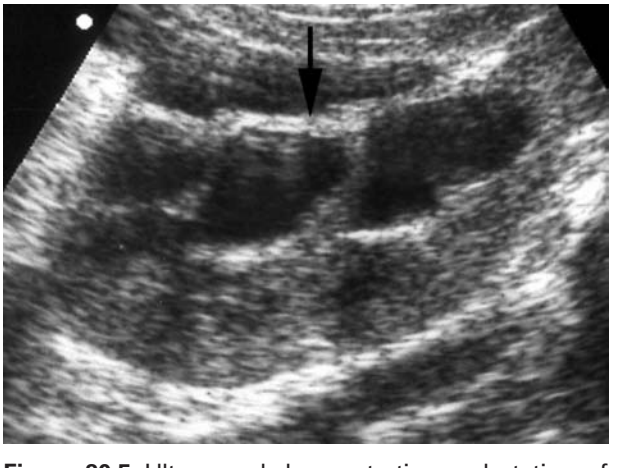

Figure 20.5 Ultrasound demonstrating malrotation of the right kidney. This results in an anterior location of the renal collecting structures (arrow) on ultrasound, rather than the usual posteromedial orientation.

Figure 20.6 CT demonstrating excessive rotation of the right kidney.

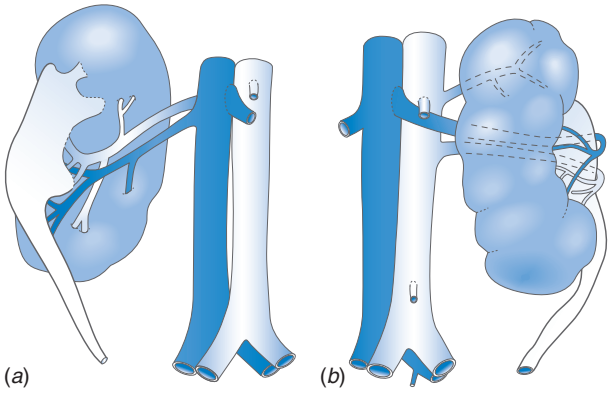

Figure 20.7 Abnormal renal rotation: (*a*) reverse rotation; (*b*) hyper-rotation. (Adapted from Weyrauch.[72])

Malrotation is usually discovered incidentally during imaging of the kidney. When symptoms occur, they are most often related to intermittent hydronephrosis and consist of abdominal pain often associated with vomiting. It is important to establish the correct diagnosis and to exclude other pathologic conditions that can produce similar distortion of the kidney. The upper third of the ureter may be displaced laterally and the renal pelvis may appear elongated, suggesting obstruction or effacement by an extrinsic mass. Obstruction may be secondary to compression of the ureter from an anomalous accessory vessel or other obstructive lesions that also occur in normally rotated kidneys. The calices are often distorted even without any associated obstruction. Helical CT can be very informative.[73] Treatment of malrotation is reserved for alleviation of associated obstruction, calculi, or infection secondary to poor drainage.

Anomalies of ascent

Renal ectopy

Renal ectopy is the term used to describe a kidney that lies outside the renal fossa. The kidney migrates cephalad early in gestation to reach its normal position. Failure of ascent can be due to a number of factors: abnormality of the ureteral bud or metanephric blastema, genetic abnormalities, teratogenic causes, or anomalous vasculature acting as a barrier to ascent.[74] During ascent, the kidney receives its blood supply from the middle sacral artery, iliac artery, and finally the aorta. The anomalous blood supply that is invariably present is dependent on the final position of the kidney and is probably not the cause of the malposition. However, the blood vessels are frequently short, rendering surgical mobilization very difficult.

The incidence of renal ectopy in postmortem studies varies from 1 in 500 to 1 in 1290.[75,76] The incidence of ectopic kidney is higher in autopsy series than in clinical studies, suggesting that many cases remain unrecognized throughout life.[74,76] There is a slight predilection for the left side, and 10% of cases are bilateral. Simple renal ectopy refers to a kidney that remains in the ipsilateral retroperitoneal space. The most common position is in the pelvis (sacral or pelvic kidney) opposite the sacrum or below the aortic bifurcation.[76] The lumbar or iliac ectopic kidney is one that is fixed above the crest of the ileum but below the level of L-2 and L-3. Crossed renal ectopy refers to a kidney that crosses the midline (see discussion on anomalies of fusion later in this chapter). Lastly, malrotation often accompanies renal ectopy (Figure 20.8).

The differentiation between a ptotic kidney and renal ectopia can be difficult, but there are several discerning features. The length of the ureter may be helpful. In renal ectopy ureteral length corresponds to the location of the kidney; in a ptotic kidney, the ureter appears redundant. The ptotic kidney is mobile and usually can be manipulated into its normal position.

Diagnosis

Most cases of renal ectopy diagnosed in childhood present with symptoms attributed to the genitourinary or gastrointestinal system, such as vague abdominal pain or renal colic secondary to ureteropelvic junction (UPJ) obstruction or urolithiasis. Urinary tract infection (UTI) is the presentation in 30% of children. The ectopic kidney may also be noted inci-

Figure 20.8 Malrotated ectopic kidney opposite lower lumbar vertebrae.

dentally, most frequently on prenatal ultrasound. A pelvic kidney is the most common finding in a fetus with an empty renal fossa and normal amniotic fluid volume.[77] They can also be detected during the evaluation of the other associated anomalies. Less often, the ectopic kidney can be detected as an abdominal mass on physical examination.

In past years, pelvic kidneys were often difficult to recognize on excretory urography because they overlie the bony structures (Figure 20.9). However, most can be now be identified by ultrasonography or radionuclide imaging.[53] Whenever a kidney is absent on ultrasound, radionuclide imaging is indicated to exclude an ectopic kidney. Voiding cystourethrography (VCUG) is recommended in all children with a diagnosis of pelvic kidney to exclude VUR, which is frequently associated with an ectopic kidney.[78] Hydronephrosis is frequently noted in ectopic kidneys.[79] Gleason et al found that half of the dilation could be attributed to ureteropelvic or ureterovesical obstruction. Obstruction in the ectopic kidney is frequently due to a high insertion of the ureter on the renal pelvis (Figure 20.10). High-grade reflux was

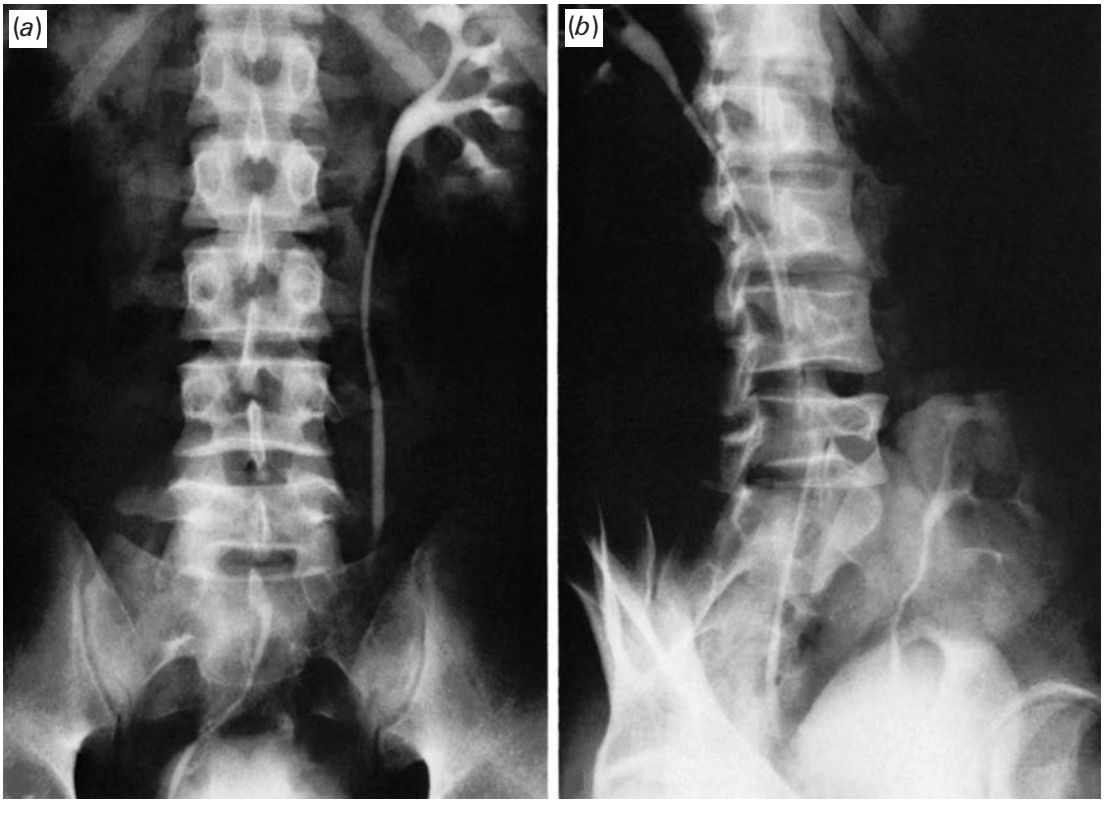

Figure 20.9 Excretory urogram in patient with a right pelvic kidney. (*a*) The short right ureter is seen overlying the bony structures. (*b*) Oblique film allows much better visualization of the collecting system and renal outline.

responsible for 26% of hydronephrotic kidneys, and extrarenal collecting system with malrotation accounted for the remainder. Diuretic renography may be needed to distinguish these abnormal pyelocaliceal patterns from UPJ obstruction. The ectopic kidney can be clearly shown on the renal scan, but the gamma camera should be place anteriorly to obtain better images (Figure 20.11). However, if the kidney is totally non-functional, an ultrasound or CT scan may be the best method of localization. MR urography is a newer modality that shows promise for detection of small poorly functioning renal units.[80] Retrograde pyelography can be used to delineate the collecting system anatomy in selected cases (Figure 20.12). Renal arteriography is now seldom performed in the patient with an ectopic kidney. Most often the kidney is supplied by multiple vessels that arise from the distal aorta, aortic bifurcation, or the iliac artery. These can be identified at the time of surgery.

Associated anomalies

The contralateral kidney is abnormal in up to 50% of patients.[74] There is a 10% incidence of contralateral renal agenesis. Associated VUR is found in 70–85% of children with an ectopic kidney.[78,81] The adrenal gland is normally positioned in most cases of renal ectopy. Genital anomalies are common, with an incidence ranging from 10% in males to 75% in females.[32,76] In males, the most common abnormalities are hypospadias and undescended testes.[74,81] Anomalies of the reproductive organs in the female include duplication of the vagina, bicornuate uterus, and hypoplasia or agenesis of the uterus or vagina.[33] These may become clinically important during pregnancy, and may require cesarean section.[32]

Anomalies of other organ systems also occur with increased frequency. Skeletal anomalies are present in up to 50% of children. The most common include asymmetry of the skull, rib abnormalities, dysplastic

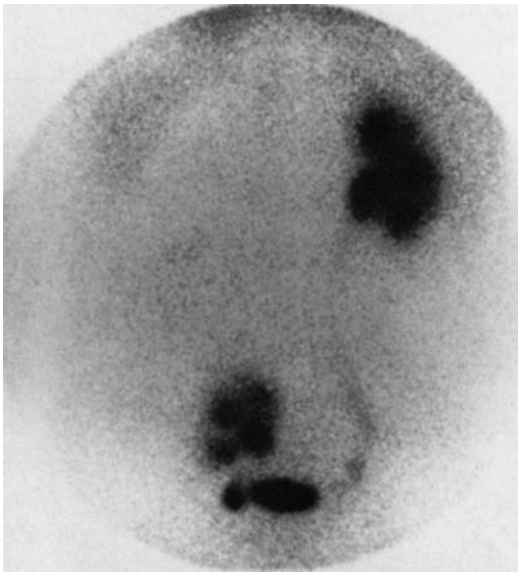

Figure 20.11 Renal scintigram of a right pelvic kidney. The camera was placed anteriorly in this patient with bilateral pyelocaliectasis.

vertebrae, and absent bones. Cardiovascular lesions were noted in 9 of the 21 children studied by Malek et al, and gastrointestinal abnormalities are found in one-third of patients.[74] Downs et al, however, reported a lower incidence of associated extragenitourinary anomalies.[32]

Management

Renal ectopy remains undiagnosed in many patients throughout life. Overall, renal disease will develop in 40% of patients with a solitary pelvic kidney.[32] The most common problem is UPJ obstruction.[79] This may be due to the malrotation and high ureteral insertion, or an anomalous vessel that partially obstructs the collecting system. Treatment should be individualized. Most cases have been managed via a transabdominal approach for pyeloplasty. The goal of surgery is to achieve dependent drainage, and in some cases ureterocalicostomy may be best. Endopyelotomy has been used in a small number of patients with some success.[82] Renal stones may develop in these kidneys (Figure 20.13). In the past, these were managed with open removal but now are amenable to extracorporeal shock wave lithotripsy (ESWL) or endourologic techniques, particularly if the ureter is dependent. An important consideration in management is that the contralateral kidney is frequently abnormal, so that every effort should be made to salvage renal tissue.

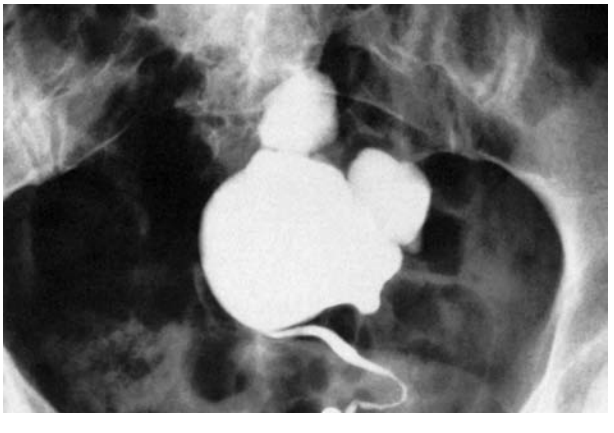

Figure 20.12 Retrograde pyelogram in a patient with a symptomatic ureteropelvic junction obstruction in a left pelvic kidney.

Thoracic kidney

Excessive cranial migration of the kidney results in a thoracic kidney. N'Guessan et al prefer to call this a 'superior ectopic kidney' because most high kidneys actually lie below the diaphragm.[83] A kidney is intrathoracic when either a portion or all extends

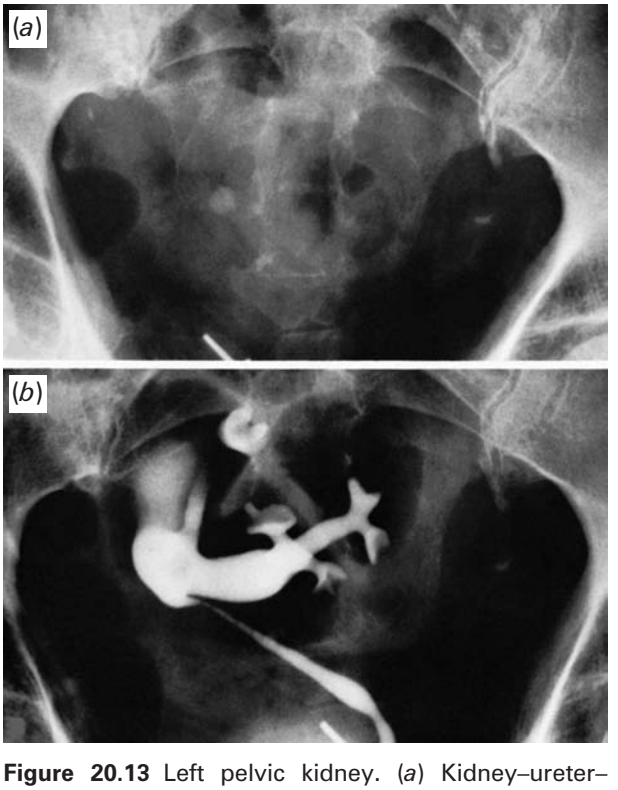

Figure 20.13 Left pelvic kidney. (*a*) Kidney–ureter–bladder (KUB) study revealed opaque calculus in the true pelvis. (*b*) Retrograde pyelogram confirmed the stone to be within the renal pelvis of the pelvic kidney.

above the diaphragm. This accounts for less than 5% of renal ectopy, with an incidence of 1 in 13 000 autopsies[75] with more than 140 cases reported.[84] The left side is more commonly involved and there is a male predominance. The condition is rarely bilateral.[83]

Renal ascent is normally complete by the 8th week of gestation. An intrathoracic kidney may be the result of accelerated ascent prior to diaphragmatic closure or delayed closure of the diaphragmatic anlage allowing continued ascent.[83,85] The renal vascular supply often arises from the normal site of origin on the aorta,[86] but may arise more superiorly. The kidney otherwise appears normal and has generally completed rotation.

In most cases, the kidney is actually subdiaphragmatic in location. A thin membranous portion of the diaphragm overlying the kidney has been described in patients examined at thoracotomy or necropsy. In the supradiaphragmatic kidney, the ureter and hilar vessels enter through the foramen of Bochdalek. The adrenal gland frequently remains caudal to the kidney in its normal location.[83] A superior ectopic kidney in association with a Bochdalek's hernia is uncommon. In this circumstance, there is herniation of other viscera through the diaphragm, and the kidney is mobile and can be easily withdrawn from the thorax.

In general, the thoracic kidneys function normally and most patients are asymptomatic. As with most renal anomalies, prenatal diagnosis is possible.[87] UPJ obstruction has been noted.[84] The condition is most often detected on routine chest radiographs as a suspected mediastinal mass. Excretory urography or CT scans confirm the diagnosis.

Anomalies of fusion

The congenital renal anomaly that produces some of the most bizarre-looking urograms is the result of fusion of two or more kidney masses. There are several proposed mechanisms. The kidneys cross the umbilical arteries as they ascend out of the pelvis. Malposition of the umbilical arteries may cause the developing nephrogenic blastemas to fuse in the midline, resulting in a horseshoe kidney. If during ascent, one kidney advances slightly ahead of the other, the inferior pole may come in contact with the superior pole of the trailing kidney. This would result in crossed ectopia with fusion. A single nephrogenic mass induced by ureteral buds from both sides could also produce crossed fused renal ectopia.[88] This latter theory, with the ureters crossing the midline, explains a solitary or bilaterally crossed ectopic kidney. Fusion of the two masses occurs early in embryogenesis, and malrotation is present in all cases.

Horseshoe kidney

The horseshoe kidney (HSK) is the most common renal fusion anomaly, with the two renal masses joined at the lower poles in more than 90% of cases (Figure 20.14). It is postulated that fusion of the lower poles occurs very early in gestation when they are in close proximity and is the result of abnormal migration of nephrogenic cells.[89] The isthmus crossing the midline joining the two kidneys consists of either renal parenchyma or fibrous tissue. The horseshoe kidney is usually positioned low in the abdomen, with the isthmus lying just below the junction of the inferior mesenteric artery and aorta. It is postulated

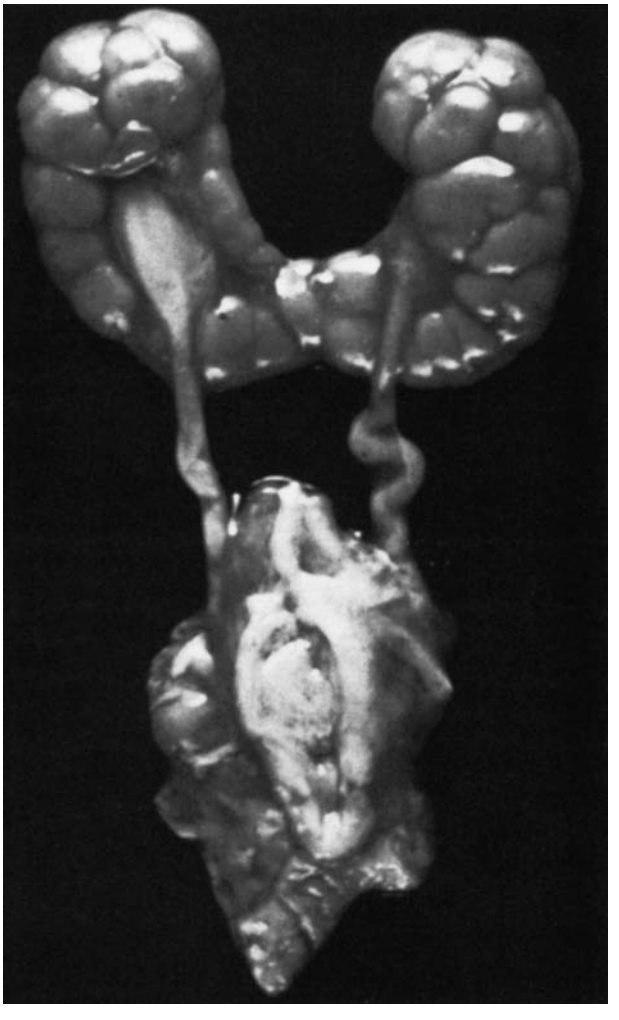

Figure 20.14 Horseshoe kidney, postmortem specimen.

that the inferior mesenteric artery obstructs the isthmus and prevents further ascent. Although usually situated anterior to the great vessels, the isthmus may cross posterior to the aorta and/or inferior vena cava.[90]

The reported incidence of horseshoe kidney varies from 1 in 400 to 1 in 1800.[70,91] The abnormality is more common in males. In autopsy series, this anomaly is found more commonly in children, which is attributed to the high incidence of associated congenital anomalies causing the demise of such children. This is in comparison to the 3.5% incidence of associated congenital malformation in adults discovered to have horseshoe kidneys. Horseshoe kidneys have been reported in identical twins and in several siblings within the same family.[92]

Diagnosis

Many horseshoe kidneys are now diagnosed on prenatal ultrasound.[77] Strauss et al reported that sonographic features are low-lying kidney, curved configuration of the kidney, tapering and elongation of the lower pole, and a poorly defined inferior border.[93] The diagnosis of the horseshoe kidney may be suspected from a plain radiograph of the abdomen if the renal outlines are visible. The classic features of HSK have been noted on excretory urography, but this is now seldom performed in children (Figure 20.15). Malrotation of the kidney is always present and is attributed to very early fusion of the kidneys before rotation is complete. The renal pelves remain anterior, with the ureters crossing the isthmus. The orientation of the calices is generally anteroposterior, but the lowermost calices invariably point towards the midline, medial to the ureter. These lower calices often overlie the vertebral column. The renal axis appears to be vertical or shifted outward, with the lower poles lying closer together than the upper poles. The course of the ureters is variable, but they often lie anterior to the pelvis. The upper ureter appears to be laterally displaced by a midline mass. Other pertinent urographic findings are low-lying kidneys, and the lower outer border of the kidney appears to continue across the midline. The radiographic appearance of a horseshoe kidney is frequently altered by associated abnormalities such as hydronephrosis and/or diminished renal function.

The diagnosis of a horseshoe kidney can be confirmed by a variety of imaging techniques, including ultrasound, CT, or MRI (Figure 20.16). In general, the fusion of the kidneys can be clearly visualized with either of these studies (Figure 20.17). Radionuclide imaging (Figure 20.18) can also be helpful in making the diagnosis when other imaging modalities are

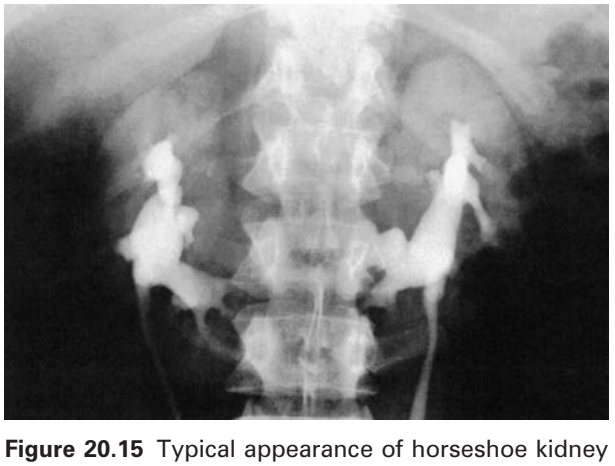

Figure 20.15 Typical appearance of horseshoe kidney on an excretory urogram.

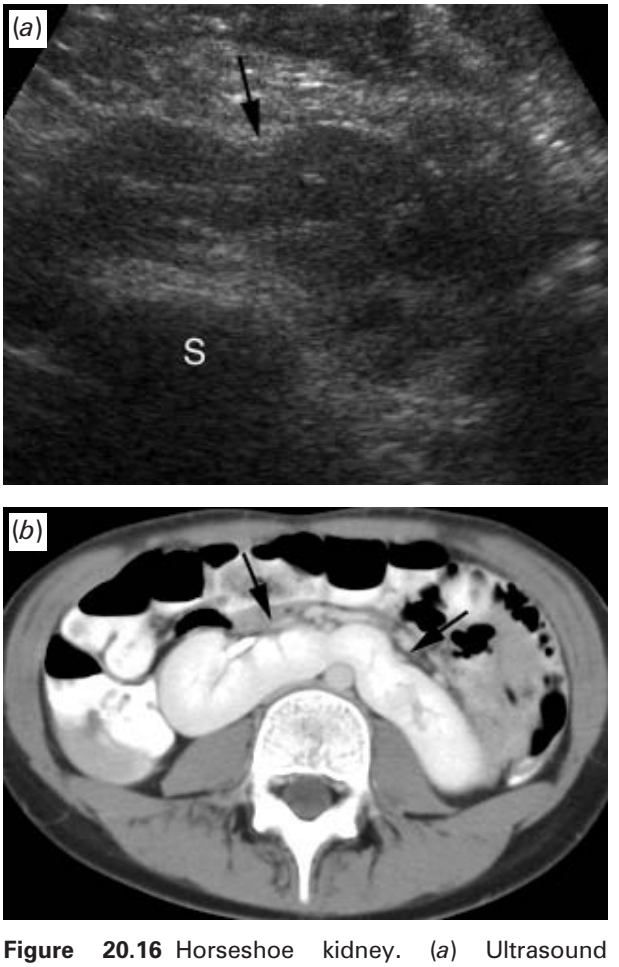

Figure 20.16 Horseshoe kidney. (*a*) Ultrasound demonstrates the isthmus (arrow), which is only partially visible anterior to the spine (S). (*b*) CT of the same patient better demonstrates the fused lower poles (arrows).

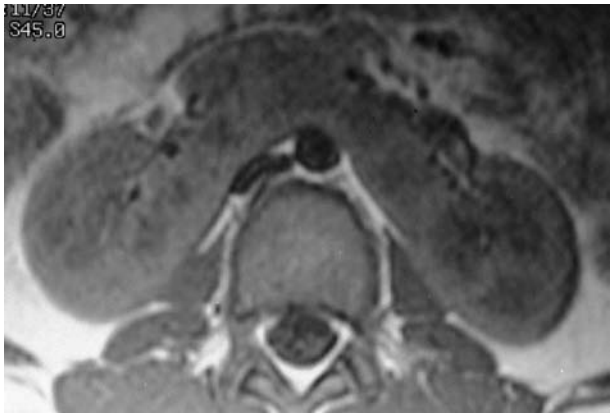

Figure 20.17 MRI of a patient with horseshoe kidney.

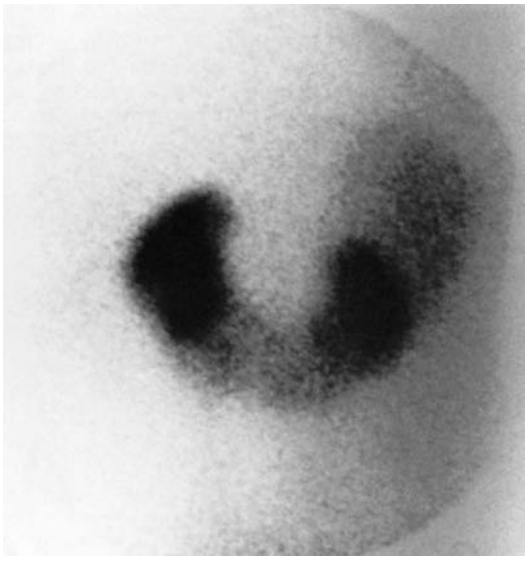

Figure 20.18 Renal scan in a patient with horseshoe kidney showing minimal function of the isthmus.

inconclusive.[94] Kao et al found that a DMSA (dimercaptosuccinic acid) renal scan identified the isthmus in 100% of children with HSK. In the past, renal arteriography was often performed before surgery to delineate the vascular blood supply. In the majority of cases, there are multiple renal vessels. The blood supply to the isthmus is particularly variable, often supplied by a separate vessel. This may arise from the aorta, common iliac, or inferior mesenteric arteries.

Associated anomalies

There is a frequent association of other anomalies in children with horseshoe kidney, especially when the horseshoe kidney is discovered in the newborn period. Zondek and Zondek examined the postmortem records of 99 individuals with horseshoe kidneys.[95] Infants who were stillborn or who died within the first year of life had a 78% incidence of other malformations. The most commonly affected organ systems were the gastrointestinal, skeletal, cardiovascular, and central nervous systems. Boatman et al reported that one-third of patients with horseshoe kidney had at least one other abnormality.[96]

Several well-known syndromes have a predisposition for HSK. Trisomy 18 is associated with a 21% incidence of renal fusion.[96,97] More than 60% of patients with Turner's syndrome have renal abnormalities, including HSK, ureteral duplication, or other minor abnormalities.[98] One study noted a 7% incidence of HSK in patients with Turner's syndrome who were evaluated with renal ultrasound scanning.[99] There is also an increased incidence of HSK in patients with neural tube defects.[100]

Other genitourinary abnormalities are also encountered with increased frequency in patients with HSK. Ten percent of patients have ureteral duplication, and VUR has been found in 10%[101] to 80% of children who undergo evaluation.[102] A more recent report by Cascio et al found VUR in 13/40 patients with HSK undergoing cystography.[103] Multicystic dysplasia[104] and autosomal dominant polycystic kidney disease have also been reported.[101] Hypospadias and undescended testes occur in 4% of the males, bicornuate uterus or septate vagina in 7% of females.[96] Retrocaval ureter has been found in association with a horseshoe kidney in six patients.[105]

Prognosis

A horseshoe kidney does not usually affect life expectancy. Nearly one-third of patients with a horseshoe kidney remain undiagnosed throughout life.[101] Most women are able to go through pregnancy and delivery without adverse effects.[106] In those patients with problems, symptoms are most often secondary to hydronephrosis, UTI, or urolithiasis. These patients generally present with vague abdominal pain. Patients can develop abdominal pain and nausea with hyperextension of the spine (Rovsing syndrome), presumably resulting from stretching of the isthmus. Operations to divide the isthmus were once performed to relieve pain, but this procedure has little merit.[101]

UPJ obstruction is the most common cause of hydronephrosis, occurring in 30% of patients diagnosed during life. Kao et al performed diuretic renog-

raphy in 22 children with HSK detected on routine screening.[94] Only 1/44 renal units, 2.3%, was found to have obstructive hydronephrosis. This suggests that most cases of obstruction are acquired over time. The obstruction may be caused by a high ureteral insertion or an anomalous renal vessel. It must be recognized that the calices may have an abnormal appearance as a result of the malrotation alone and that not all of these kidneys are obstructed. Kao et al[94] showed that 25% of renal units had some stasis prior to administration of diuretic. In some children, the upper urinary tract dilatation may be secondary to VUR (Figure 20.19).

Urolithiasis develops in 20% of patients with a horseshoe kidney. The increased risk of stones is attributed to stasis secondary to hydronephrosis, but metabolic factors should not be overlooked.[107] A recent multicenter study showed that all patients with HSK and calculi had some metabolic abnormality.[108] Hypercalcuria, hypocitraturia, and low urine volumes were the most common defects.

Over 100 cases of renal malignancy have been reported in patients with horseshoe kidney,[109] with a number of tumors arising from the isthmus.[110] There appears to be an increased incidence of renal pelvic tumors and nephroblastoma in patients with HSK compared with the general population.[110,111] Wilms' tumor is the second most common tumor found in horseshoe kidneys. In a review of National Wilms' Tumor Study Group (NWTSG) patients, Mesrobian et al found that there was a sevenfold increased risk of a Wilms' tumor developing in patients with a horseshoe kidney.[112] Neville et al updated the NWTSG experience and identified 41 children with Wilms' tumor arising in a HSK.[113] The diagnosis of horseshoe kidney was missed preoperatively in 13 patients, even though CT was performed in the majority.

Figure 20.19 Horseshoe kidney. Voiding cystourethrogram demonstrating high-grade vesicoureteral reflux into the left renal moiety. Note the medial pointing calyx in the lower pole extending into the isthmus.

Management

Correction of UPJ obstruction is the most frequent indication for surgical intervention in a patient with a horseshoe kidney. The goal of dependent drainage following pyeloplasty may be difficult to achieve in these patients. Routine division of the isthmus was once recommended to avoid having the ureter cross the isthmus. However, it has become clear that the isthmus does not contribute to the obstruction and should not be routinely divided.[114] Donahoe and Hendren report that the kidneys remain in their original position following symphysiotomy because of fixation by the abnormal vasculature.[115] An extraperitoneal flank approach is utilized for unilateral operations. In those patients requiring bilateral procedures, a transperitoneal approach may be preferable in order to allow operation on both sides at once. Endourologic management, percutaneous endopyelotomy, or laparoscopic pyeloplasty are other options for these patients, but experience is limited.[82,116]

Treatment of renal calculi will be dependent on stone burden. Most patients with small renal stones can be managed with ESWL.[117] Calculi >2 cm are best managed percutaneously. Upper pole access and flexible nephroscopy are frequently required.[118]

Crossed renal ectopia

Crossed renal ectopia is the second most common fusion anomaly. The etiology of crossed ectopia is uncertain, although several theories have been expressed.[24] The ectopic kidney crosses the midline to lie on the opposite side from its ureteral insertion into the bladder (Figure 20.20). The four varieties of crossed renal ectopia are illustrated in Figure 20.21. The incidence of crossed ectopia has been placed at 1 in 7000 autopsies.[120] Crossed renal ectopia with fusion is the most common type and accounts for

Figure 20.20 Crossed ectopia, with the right kidney crossing midline and fused to the lower pole of the left kidney.

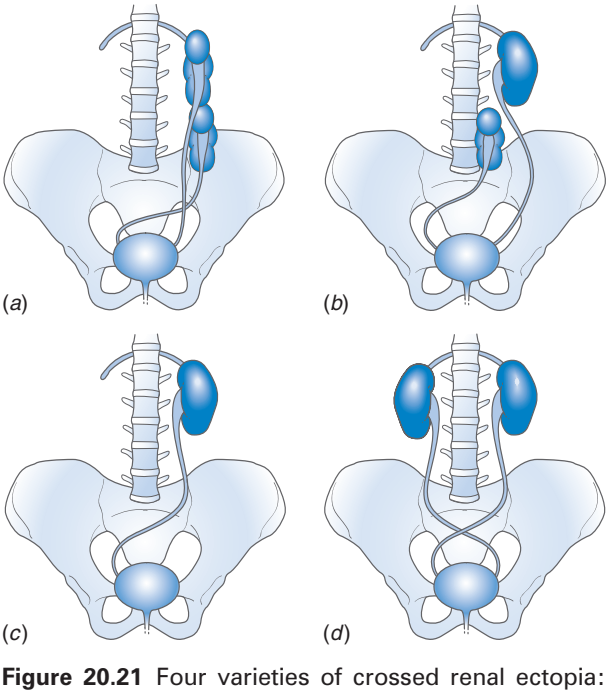

Figure 20.21 Four varieties of crossed renal ectopia: (*a*) with fusion; (*b*) without fusion; (*c*) solitary; and (*d*) bilateral. (Redrawn from McDonald and McClellan,[119] as reproduced by Abeshouse and Bhisitkul.[120])

85% of the cases. Crossed ectopia without fusion represents fewer than 10% of all cases, and solitary crossed ectopia and bilateral crossed ectopia are exceedingly rare.[119,121] With all of these abnormalities, there is a slight male predominance and crossing from left to right occurs more frequently than right to left.

The many variations of fusion can produce bizarre radiographic pictures, and determination of the exact type of crossed ectopia can be difficult. McDonald and McClellan described six different varieties of crossed ectopia with fusion (Figure 20.22).[119] The most common form is unilateral fused type with inferior ectopia, in which the upper pole of the crossed kidney is fused to the lower pole of the normally positioned kidney. The renal pelves remain in their anterior position, representing failure to complete rotation. The second most common type is the sigmoid, or S-shaped, kidney. The crossed kidney is inferior, but both kidneys have completed their rotation so that the two renal pelves face in opposite directions. The fusion of the two kidneys probably occurs later, after axial rotation is completed.

The other four types of fusion are much less common. The lump, or 'cake', kidney and the 'disk' kidney both involve extensive fusion of the two renal masses. In an L-shaped kidney, the crossed kidney assumes a transverse position. The least common type is the superior ectopic kidney, in which the crossed ectopic kidney lies superior to the normal kidney. The two kidneys may also fuse side to side and ascend together to the renal fossa (Figure 20.23).

Diagnosis

The classification described above was devised to stratify the patients in some logical fashion. There is a spectrum of abnormalities, and it is often difficult to categorize patients based on urographic findings. It also can be difficult to distinguish between crossed ectopia with fusion from crossed renal ectopy without fusion. This distinction may be possible on ultrasound or excretory urography if the two renal masses are widely separated. CT and MRI are more likely to establish the correct diagnosis. Radionuclide imaging is also useful.

The vascular supply to these kidneys is quite variable. Renal arteriography often demonstrates multiple anomalous branches to both kidneys arising from the aorta, or common iliac artery. Rarely will the renal artery cross the midline to supply the crossed kidney.[122]

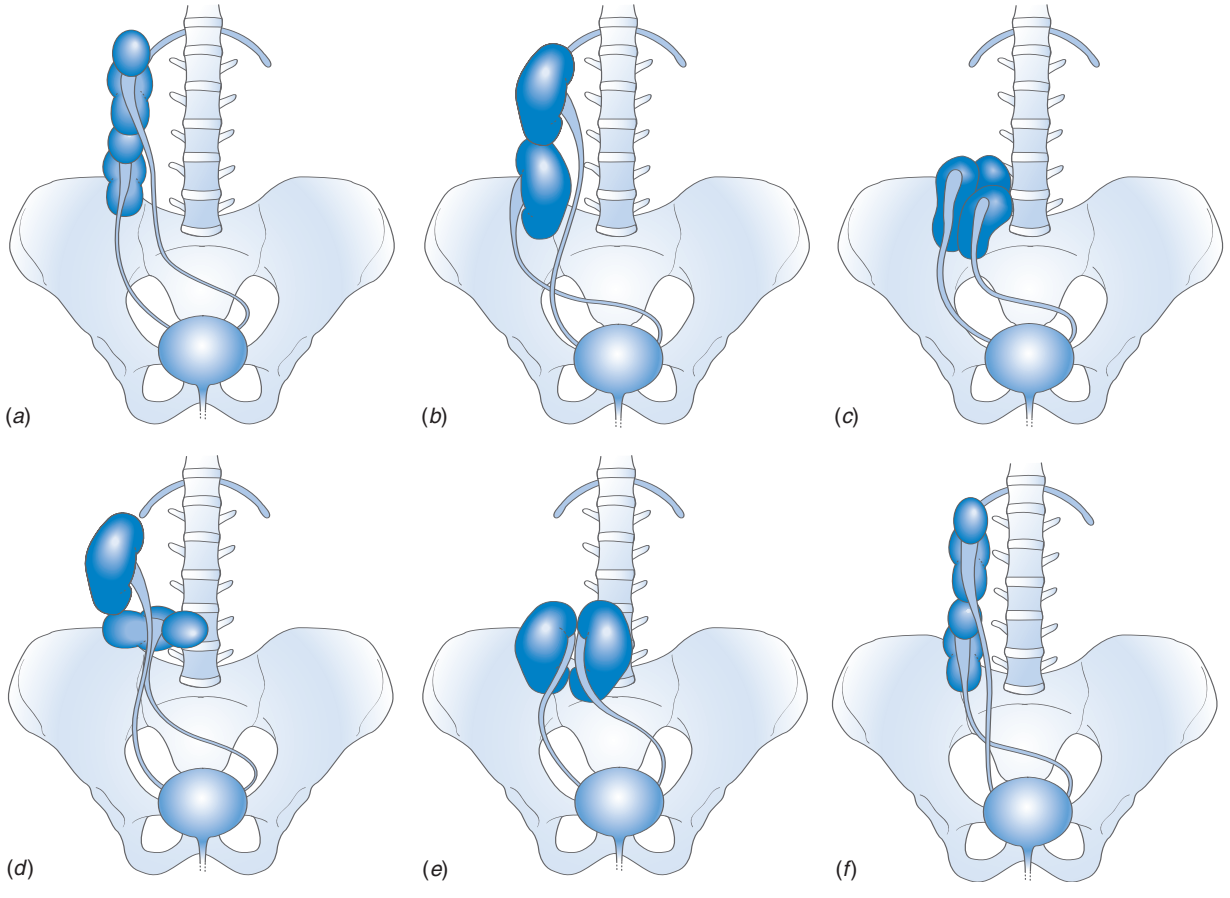

Figure 20.22 Six varieties of crossed renal ectopia with fusion: (*a*) unilateral fused kidney, superior ectopia; (*b*) sigmoid or S-shaped kidney; (*c*) 'lump' kidney; (*d*) L-shaped kidney; (*e*) 'disk' kidney; and (*f*) unilateral fused kidney, inferior ectopia. (Redrawn from McDonald and McClellan,[119] as reproduced by Abeshouse and Bhisitkul.[120])

Associated anomalies

There is an increased incidence of other malformations, including orthopedic or skeletal anomalies, imperforate anus, and cardiovascular anomalies.[120] A higher incidence of genital abnormalities is found in patients with solitary crossed ectopia similar to that found in unilateral renal agenesis.[78]

The ureter in the crossed ectopic kidney usually enters the bladder and its orifice is only rarely ectopic.[120] The most commonly associated abnormality is VUR, which is frequently noted in the ectopic kidney.[78,81] VCUG should be performed in all of these patients. Less common problems include UPJ obstruction, renal dysplasia,[123] and renal tumors.[124]

Prognosis

Most patients with crossed renal ectopia are discovered incidentally, often by antenatal sonography when two kidneys are not identified.[77] When symptoms do occur, they are often related to infection and obstruction. Abeshouse and Bhisitkul reported that one-third of patients had pyelonephritis and one-quarter had hydronephrosis (Figure 20.24).[120] The caliceal dilatation and distortion may be secondary to the malrotation or the presence of VUR. Urolithiasis has been found in up to one-third of patients.[97] Mininberg et al reported one infant who presented with hypertension secondary to a vascular lesion.[125] Other patients may be found to have an abdominal mass on physical examination or during surgical exploration. It is particularly pertinent in the patient with a fused pelvic kidney to recognize that this is the total functioning renal parenchyma.

Fetal lobulation

Fetal lobulation is commonly found in children and represents a persistence of normal fetal development (Figure 20.25). Another term used to describe this is

Figure 20.23 Crossed fused ectopia. Intravenous pyelogram of a child with crossed ectopia, without obstruction.

'renal' lobation, because it designates the larger renal lobe (pyramid plus surrounding cortex) rather than the lobule (medullary ray and surrounding glomeruli).[70] Fetal lobulation is found at autopsy in 17.6% of children and in 3.9% of adults. This condition is of no clinical importance, and should be recognized as a normal variant. Radiographically, it may appear as small notches in the renal margin that are placed midway between the calices.

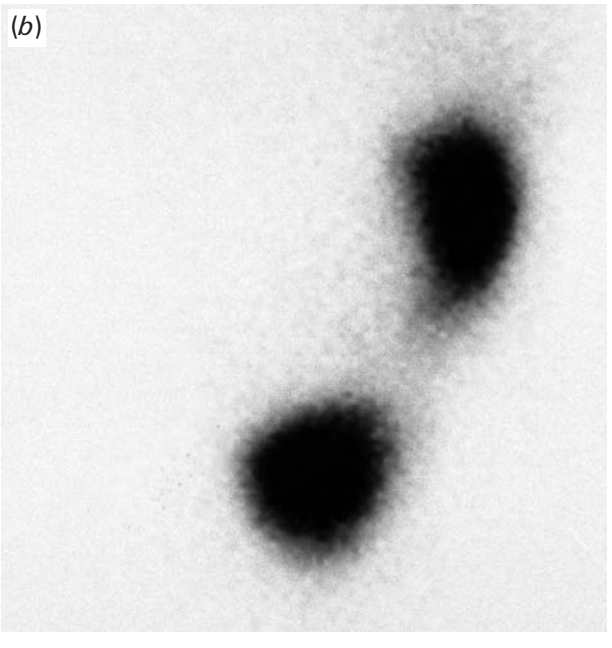

Figure 20.24 Crossed fused ectopia. (*a*) The left kidney crosses the midline. The presence of fusion is difficult to ascertain with confidence on this intravenous pyelogram. Obstruction is noted in the normally positioned right kidney. (*b*) ^{99m}Tc MAG3 radioisotope scan shows increased tracer activity in the right abdomen only.

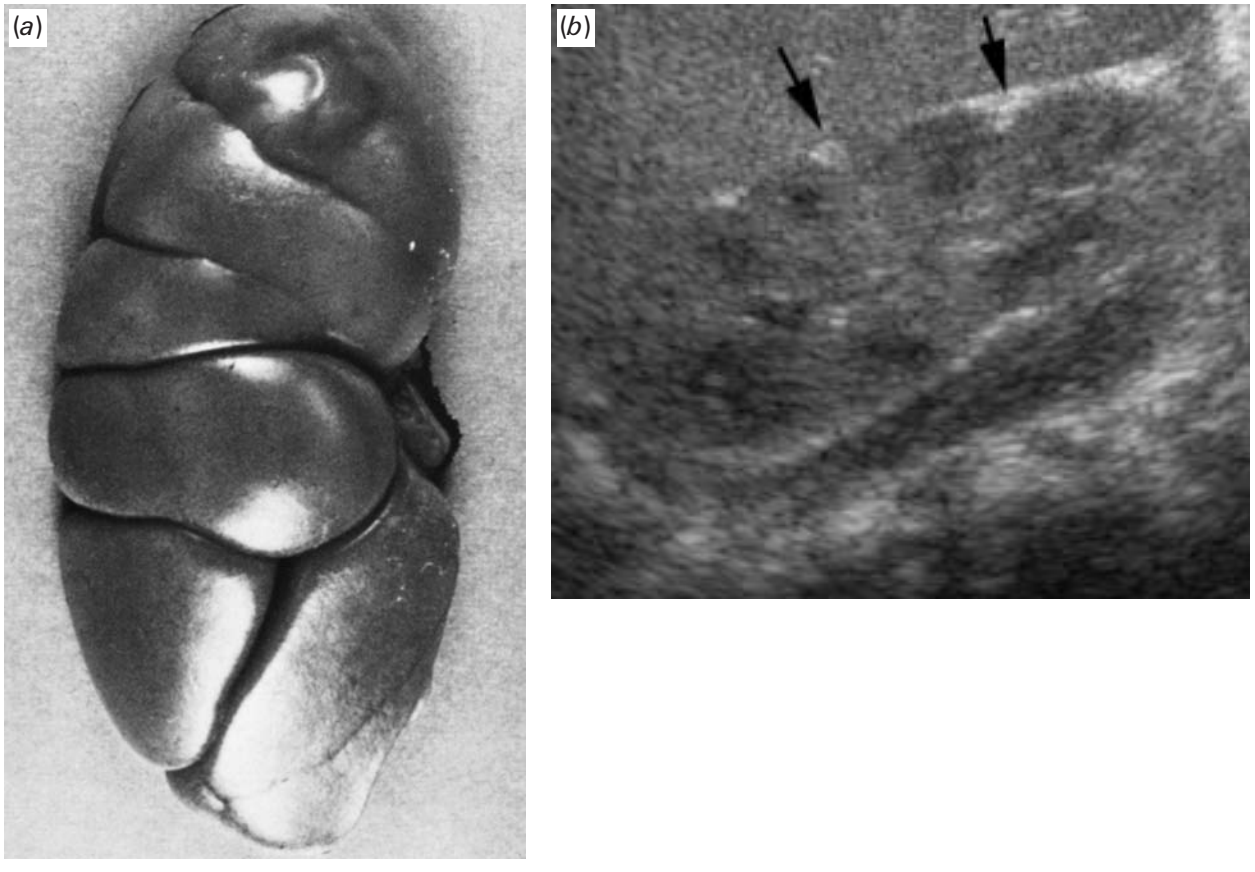

Figure 20.25 Fetal lobulation of the kidney. (*a*) Gross image. (*b*) Ultrasound: note the regularly spaced indentations along the margin of the kidney (arrows) in this normal child.

Fetal and neonatal renal function

21

Billy S Arant Jr

Introduction

The developing mammalian kidney is a remarkably complex organ. Although it has been characterized as small, immature, limited, and imbalanced and, as such, an impediment to the medical management of sick infants, this view is unwarranted. When it was first recognized that glomerular filtration rate (GFR) corrected for the body size of newborn infants was less than values measured in the adult,[1] the notion of limited renal function was introduced. Although the bulk of published studies on the various functions of the neonatal kidney seem to support limitation, many of these studies were misinterpreted and seemed to have conformed to the bias prevalent at the time.

It is somewhat difficult to imagine how the species survived the stress of fetal adaptation to the functional integrity of postnatal life if the neonatal kidney were indeed limited in its functional capacity. Many premature infants weighing <1000 g at birth survived even in the 1930s to become healthy infants long before the availability of supportive measures now referred to as neonatal intensive care.[2] Recent human and experimental animal studies provide some enlightenment and confirm the essential and unique role of the kidney at any stage of viability once the umbilical blood flow is interrupted at birth.

The kidney of the human neonate functions qualitatively like the adult kidney and is more than adequate to support functional development and growth of the infant following birth, at least within limits. These limits, however, are often exceeded by the demands imposed during the treatment of sick infants when most clinical decisions are made without concern for kidney function. Too often, perhaps, it is easier to fault the kidney because it is small rather than to understand the essence of its supporting role in health and disease. Failing to appreciate the unique responses of the neonatal kidney will, on occasion, compromise clinical decision making, especially when prescribing fluid therapy[2] and drugs eliminated primarily by renal excretion.[3,4]

Morphologic development

The human metanephros is formed about the 5th week after conception, when the sequential branching ureteric bud contacts the caudal mesenchyma and induces glomerulogenesis. All glomeruli are contained within the cortex. The first ones formed occupy a juxtamedullary position and have the longest loops of Henle. The ureteric bud forms the collecting duct for each nephron and continues to branch in a centrifugal pattern until 20 weeks of gestation. New glomeruli are formed until 34–36 weeks after conception when each kidney will contain approximately one million nephrons (Figure 21.1). When birth occurs prematurely, glomerulogenesis continues. But there is speculation that the total number of glomeruli at maturity may be deficient and contribute to morbidity, mainly hypertension and renal insufficiency in later life due to glomerular hyperfiltration.[6] Glomerular filtration is evident after 8 weeks' gestation, but the ureter may not be entirely patent until the 11th week. Ureteral obstruction is thought to provoke dilation of the proximal collecting system, the renal pelvis, and calices. The layers of smooth muscle and elastic fibers in the ureter are laid down after 36 weeks' gestation and continue to form for 8 weeks after birth at term. If there is an essential role of the fetal kidney, it must be to contribute the majority of amniotic fluid after the first trimester of pregnancy.

Physiologic adaptation at birth

Body composition

From the moment of conception, when the composition of the fertilized ovum is 99% salt and water,

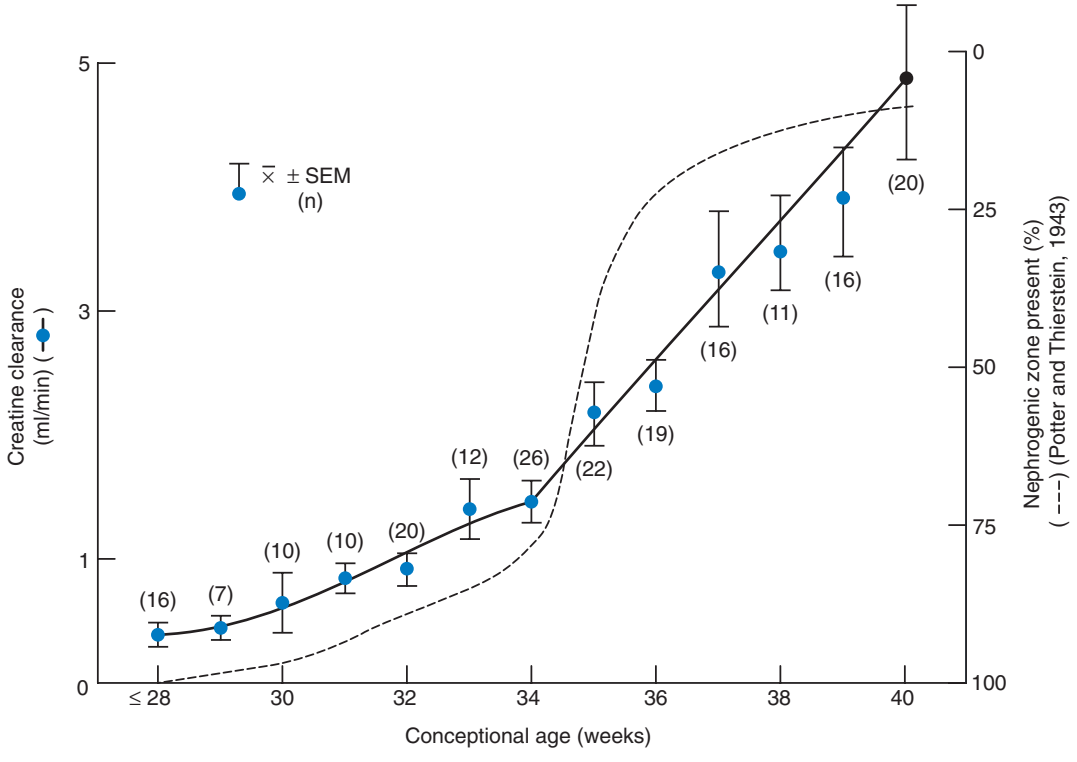

Figure 21.1 Developmental pattern of changes in creatinine clearance [glomerular filtration rate (GFR)] and the disappearance of the nephrogenic zone of the renal cortex compared with the conceptional age of human infants. (From Arant,[5] with permission.)

there is a gradual reduction in the relative body content of water and minerals with age. While the total amounts of minerals and water provided by the placenta increase as the fetus grows, organs are formed and tissue growth occurs which incorporate these elements into cytoplasm and extracellular matrix. The higher salt and water content of the fetus assures a relative abundance of extracellular fluid, which decreases from 60% of body weight at the beginning of the last trimester to 40% at birth; extracellular fluid represents only 20% of body weight in the adult.[7] Therefore, whether birth occurs before or at term, essentially all neonates have an expanded extracellular fluid volume that allows them to survive naturally without intake for a few days postnatally as the volume of the mother's breast milk increases. Extracellular fluid volume expansion in the neonate influences renal function just as it does in the adult. When birth occurs at term, the total body water content has been reduced to 75% and the sodium content has decreased from 120 mmol/kg body weight at 8 weeks after conception to 85 mmol/kg.[8] During the first week of life, there is an additional reduction in the relative body water and sodium content, mainly through urinary losses and, thus, extracellular fluid volume is reduced further. In premature infants, this abrupt reduction in total body water and sodium following birth is more pronounced and represents losses of up to 25% of body weight as water and 14 mmol/kg of sodium with no change in plasma sodium concentration or blood pressure.[9–11]

Cardiovascular hemodynamics

During fetal life, systemic vascular resistance is kept very low except in the pulmonary and renal circulations, where vascular resistance is high since neither organ contributes directly to the viability of the fetus.[5] The explanation for the regulation of the differences in these specialized circulations may be the local formation of vasoactive substances that cause vascular smooth muscle to contract (angiotensin) or relax (prostaglandins and nitric oxide). Cardiac output in the fetus is high and varies only with heart rate since stroke volume is always at a maximum.[12] Moreover, blood volume in the fetus and very preterm infant may be as high as 120 ml/kg body weight compared with 75 ml/kg in the adult.[13] With both cardiac output and blood volume high, how can blood pressure be so low? Normal mean arterial pres-

sure for a preterm infant is only about 25 mmHg. The answer, therefore, must come from the balance of forces that regulate vascular resistance. There is an inverse relationship between blood volume and diastolic blood pressure in normal human adults.[14] Moreover, when fetal animals or preterm infants have their blood volumes expanded by colloid or whole blood, blood pressure does not increase and may actually decrease in some cases.[15,16] Even when the volume of blood in the placental circulation is transfused into the neonatal circulation, which could be up to 30 ml/kg, there is no sustained rise in the infant's blood pressure or right atrial pressure.[17] At birth, the placental circulation is interrupted, the lungs are expanded with the first breaths by the infant, and pulmonary vascular resistance decreases to allow oxygen transfer across the alveolus into the blood. Then, the ductus arteriosus closes when the oxygen tension in arterial blood has increased sufficiently to cause the specialized smooth muscle in that structure to constrict. Systemic vascular resistance and blood pressure in the neonate gradually increase over the first year of life to a maximum normal blood pressure of 104/58 mmHg (95th percentile for age and sex).[18]

Renal blood flow

Renal blood flow (RBF) and its intrarenal distribution have been the subject of many investigations. Few of these studies provided results that were reproducible or explanations which were entirely satisfactory. Whereas GFR can be measured easily by clearance methodology, the only technique for measuring RBF in human infants is still the clearance of para-aminohippurate (PAH). After concluding that RBF measured by PAH clearance was disproportionately low in newborn infants, which was part of the reason for misrepresentation of newborn kidney function, it was later learned that the extraction of PAH by the newborn kidney was less than half that of the child or adult.[19] When corrected for the PAH extraction rate, RBF and the filtration fraction or the ratio of GFR:renal plasma flow was 0.20, the same as the normal value in the adult.

RBF in the full-term infant increases from 290 ml/min/1.73 m^2 at birth to 750 ml/min/1.73 m^2 by 8 months of age.[19,20] This increase in RBF occurs as renal vascular resistance (RVR) decreases. No actual measurements of RVR have been reported for human infants, even though calculations made using average blood pressure for age (Figure 21.2) provide the same pattern of developmental change as reported in the pig[22] and dog.[23]

There would appear to be a direct relationship between changes in RVR and the intracortical distribution of RBF during development. While it was once believed that there was a centrifugal redistribution of blood flow within the renal cortex, the actual pattern of blood flow distribution follows the distribution of functioning or filtering nephrons.[24] Studies that fostered the former notion were conducted in anesthetized animals following acute surgical preparation, a situation known to alter total RBF and reduce outer cortical blood flow by activating the intrarenal renin–angiotensin system.[25] More than half the glomeruli reside in the outer cortex at birth, and appropriately done studies have demonstrated a predominance of blood flow distribution to this area.[26] Further growth of the kidney is achieved mainly by lengthening of proximal convoluted tubules, which are interposed between glomeruli. At maturity, the glomeruli are evenly distributed throughout the cortex and the blood flow to each cortical region is similar.

Once it was thought that the kidney only responded to circulating hormones that affected its various functions. For instance, that renin, produced in juxtaglomerular cells and released from the kidney, acted on angiotensinogen made by the liver to synthesize angiotensin I. This, in turn, was acted on by angiotensin-converting enzyme (ACE) in the pulmonary circulation to release the vasoconstricting hormone angiotensin II (ANGII) into the arterial circulation. However, the intrarenal production of vasoactive substances is now well known. The kidney is capable of producing large quantities of ANGII on its own, as can isolated, bloodless glomeruli.[27] Also, molecular studies have demonstrated mRNA for renin, angiotensinogen, and ACE. In micropuncture studies of the rat kidney, ANGII concentrations were found to be 1000-fold higher in efferent arteriolar blood and proximal tubular fluid than in the systemic circulation.[28] Moreover, the kidney and glomeruli contain the enzymes for synthesizing ANGII by pathways other than ACE.[27]

What does the kidney do with all the ANGII it produces? Both circulating levels of plasma ANGII and the urinary excretion of ANGII and its metabolites are increased in human and canine neonates.[29] Moreover, the pattern of change in the urinary excretion of ANGII parallels the change in RVR following birth. In addition to effecting resistance in the renal microcirculation to regulate GFR, ANGII exerts a major

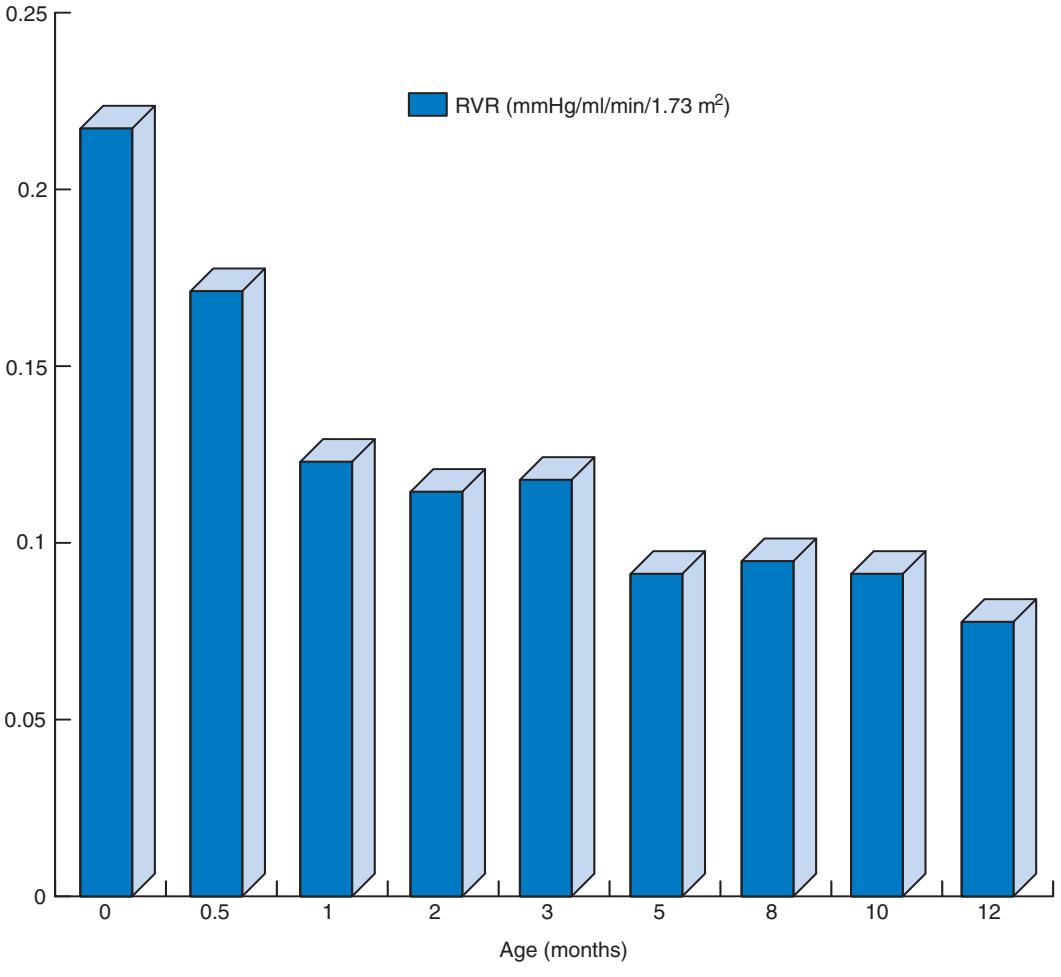

Figure 21.2 Decrease in renal vascular resistance (RVR) with the postnatal age of human infants born at term and studied during the first year of life. Renal blood flow was estimated from extraction-corrected clearances of PAH.[19,20] Age-related normal values for hematocrit and mean arterial pressure[21] were used for calculations.

influence over proximal tubular mechanisms, particularly sodium reabsorption.[30] ANGII is rapidly metabolized within the kidney because the high concentrations in arteriolar blood and proximal tubular fluid are not found in either renal venous effluent or distal tubular fluid.[28] Moreover, concentrations of ANGII in tissue-free incubation medium remain constant with time but decrease in the presence of isolated glomeruli.[27] Very little ANGII can be measured in bladder urine, but its metabolites are more abundant. Finally, ANGII is an important growth factor that, in some way, may be critical to the morphologic development of the kidney. When ACE inhibitors are given to pregnant women, both the structure and function of the fetal and neonatal kidney are altered.[31] In disease states, such as diabetic nephropathy, chronic glomerulonephritis, or chronic pyelonephritis, progressive renal scarring and deterioration of renal function can be slowed dramatically by inhibiting ANGII production or effects. This beneficial effect is mediated not only by lowering blood pressure and reducing glomerular hyperfiltration but also by reducing the deposition of collagen in diseased renal parenchyma.

Vasoactive factors that oppose the vasoconstricting effects of ANGII include prostaglandins, particularly PGE_2 and prostacyclin, and nitric oxide. It is difficult to separate the vasodilating effects of one from the other. It may be that the prostaglandins are the mediators of nitric oxide production by the vascular endothelium, but the renal vascular and tubular responses to nitric oxide have not been studied in the developing kidney or newborn infant. Prostaglandins also mediate the effects of loop diuretics[32] and reduce tubular responsiveness to arginine vasopressin.[33] When an inhibitor of prostaglandin synthesis is

administered, therefore, the vasoconstrictor effect of ANGII is unmasked and RVR increases.[34] This is clinically apparent when a non-steroidal anti-inflammatory drug (NSAID) is given to a patient whose endogenous ANGII synthesis is elevated, as in dehydration. If watched for, there will usually be an increase in blood pressure, a decrease in GFR, and oliguria or even anuria, which does not respond well to furosemide or fluid administration. The opposite is seen when an ACE inhibitor or AT-1 receptor blocker is given to someone whose endogenous synthesis of prostaglandins, particularly prostacyclin, is increased, as in the neonate or a patient with Bartter syndrome. This patient may become hypotensive and renal perfusion pressure reduced.

Catecholamines are produced in significant amounts in the fetus and newborn infant but their impact on RBF, except in hypovolemic states, is difficult to demonstrate in clinical studies. Based on no appropriate data, the recommendation has been made for years that low doses (5 μg/kg/min) or 'renal doses' of dopamine be infused to treat infants with hypotension or hypoperfusion. The benefit of such therapy was extrapolated from studies of adults in various shock-like states.[35] Studies in healthy newborn animals have not reported a consistent beneficial effect of a renal dose of dopamine.[36] Although dopamine therapy may be associated with improved urine output and GFR, the effect probably is mediated through an improvement in cardiac output or blood pressure that, in turn, improves RBF, GFR, and urine volume.

Glomerular filtration rate

GFR estimated in the human fetus as early as 20 weeks' gestation[37] or measured at birth in minimally stressed infants from 24 weeks' gestation[38] has been reported to be around 0.2 ml/min, which is only about 5 ml/min/1.73 m^2 and does not increase significantly above this level until a postconceptional age of 34 weeks has been reached. This pattern of change has been measured and is identical whether the fetus remains in utero or continues its development after a premature birth[38] (Figure 21.3). In other words, the infant born after 34 weeks' gestation will exhibit a 5–7-fold increase in GFR during the first week of life, but the preterm infant born at 26 weeks' gestation will have no appreciable increase in GFR for 8 weeks. A similar developmental change in GFR has been reported to occur in every mammalian species studied.

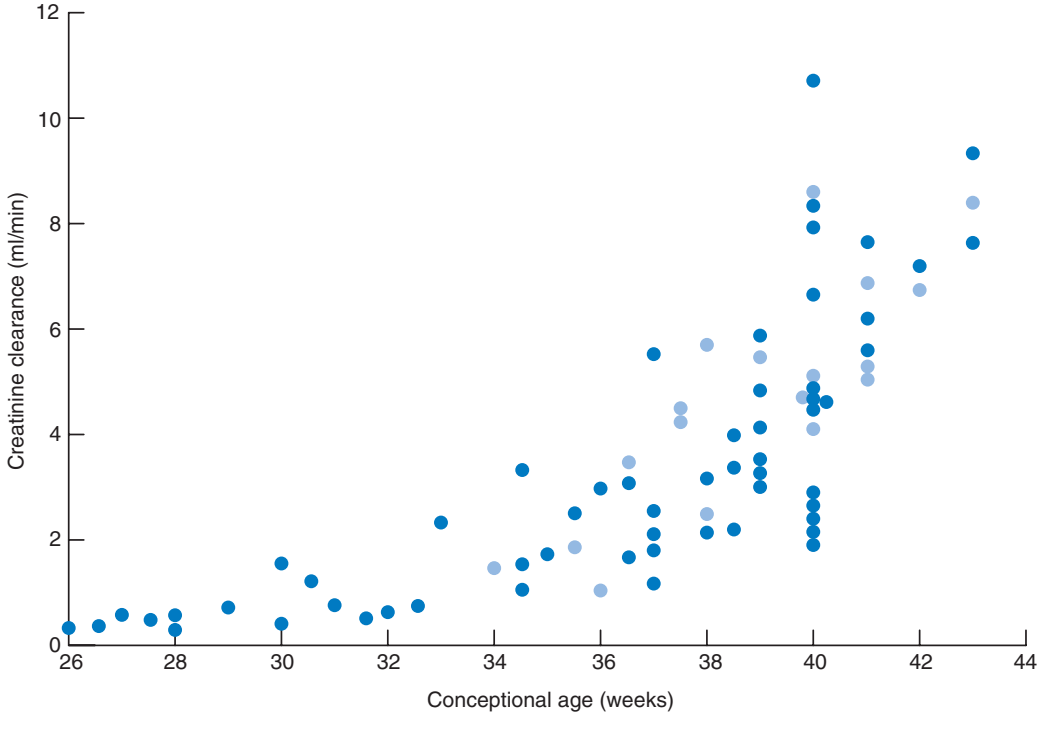

Figure 21.3 Creatinine clearance [glomerular filtration rate (GFR)] compared with conceptional age of infants from birth. Studies performed within 48 h of birth; ●, studies done at weekly intervals following birth; ●, regression analysis confirmed a non-linear relationship expressed best as an exponential equation. (From Engle and Arant,[39] with permission.)

The average GFR in the normal adult is 125 ml/min, which is achieved during adolescence when the average adult body surface area is 1.73 m^2. After 6 months of age, however, the absolute value for GFR (ml/min) can be corrected for a body surface area of 1.73 m^2 in any infant or child and compared, more conveniently, to the mature value of about 125 ml/min/1.73 m^2.[1]

Following some, as yet unidentified, biologic signal, RVR rapidly decreases and GFR increases close to the time when nephrogenesis is completed which, in the human, is at 34–36 weeks[38,39] (see Figure 21.1). This developmental phenomenon is mediated through changes in RVR and, probably, by changes in the intrarenal production of vasoactive substances such as ANGII, prostaglandins, and nitric oxide. Therefore, any treatment that alters the synthesis of these substances can change the developmental pattern, at least temporarily. For instance, a preterm neonate given indomethacin to effect closure of a patent ductus arteriosus will have a decreased GFR[40] and may have an impaired ability to increase GFR until the pharmacologic effects of the drug have diminished. Even more dramatic are the structural changes in the renal parenchyma, acute renal failure, and refractory hypotension seen in neonates whose mothers took drugs which interfered with production of angiotensin II–ACE fetopathy.[41]

GFR in the infant can be measured directly by a clearance technique that requires a timed urine collection and one or more blood samples, using either endogenous creatinine or an exogenous marker such as inulin or iothalamate, infused intravenously. Both timed urine collections and multiple blood samples are difficult to obtain in neonates. While many have turned to radioisotopic techniques to estimate GFR in adults, there are no normal data published for infants. Nuclear medicine studies often report the fraction of total uptake by the left or right kidney and interpret the result as a percentage of total kidney function, but this methodology provides no actual estimate of GFR.

Perhaps the most clinically useful estimate of GFR in neonates is a serial change in serum creatinine concentration compared with the pattern of change with postconceptional age expected for a normal infant. The newborn infant's serum creatinine concentration is nearly identical to maternal values, even if the infant's kidneys do not function at all.[42,43] GFR in infants born after 34 weeks' gestation should be expected to increase greatly, and *serum creatinine concentration will be reduced by 50% during the first week of life*[44] (Figure 21.4). In contrast, the infant born before 34 weeks' gestation is not expected to decrease the serum creatinine concentration until a postconceptional age of 34 weeks has been achieved because the tightly controlled GFR is sufficient only to excrete the creatinine produced each day by the infant, i.e. 8 mg/kg/day;[44] the creatinine accumulated during fetal life and distributed in total body water cannot be reduced appreciably before GFR increases at around 34 weeks after conception. The normal serum creatinine concentration should be ≤0.4 mg/dl by the end of the first month of life in infants born at term,[45] but preterm infants may not reach this level until 3 months of age[43] (see Figure 21.4). Thereafter, a doubling of serum creatinine concentration reflects a reduction in GFR by 50%.

It may be easier to estimate GFR from serum creatinine concentration and the infant's length, which, when factored with a constant number (K), can provide a reasonable assessment of GFR. The formula derived by Schwartz et al is:

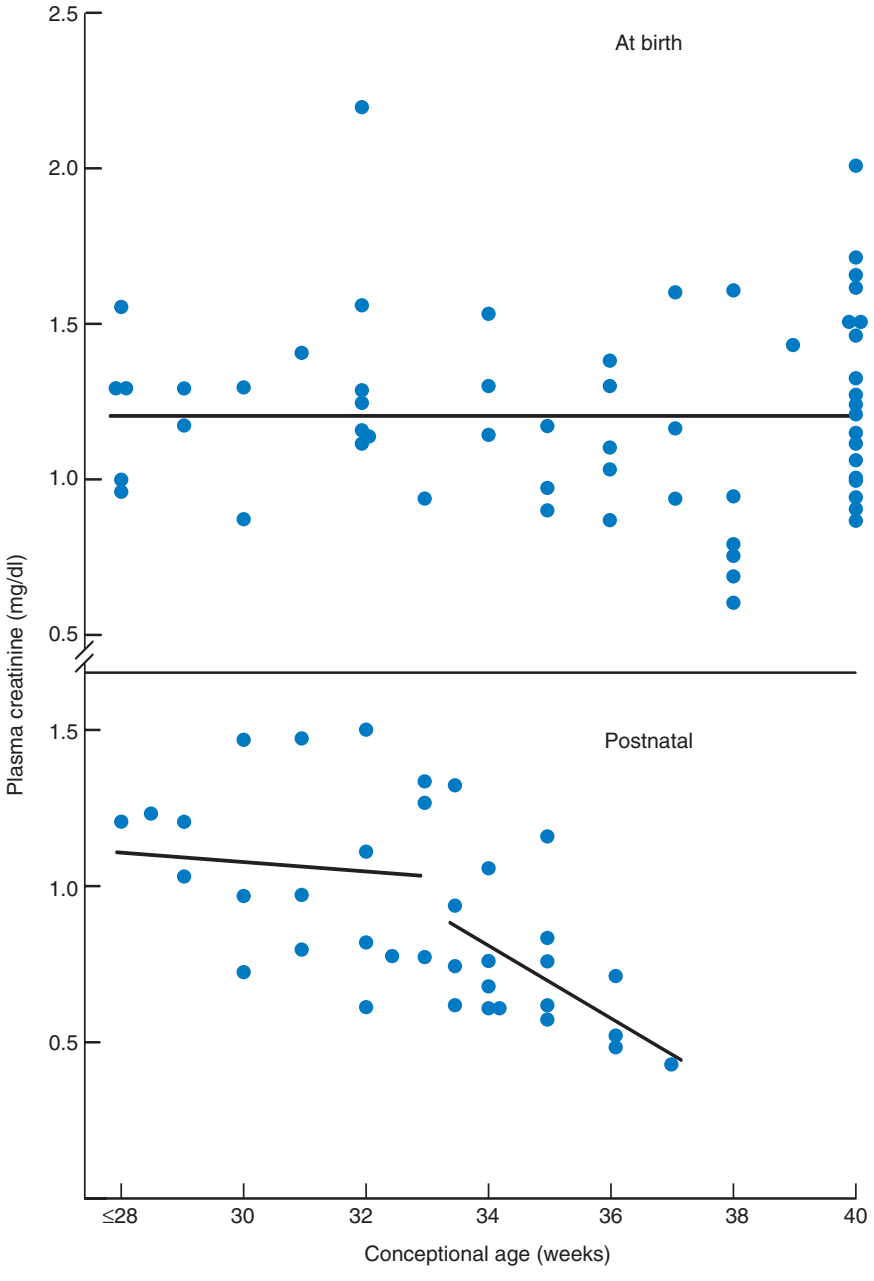
$$\text{GFR (ml/min/1.73 m}^2) = \frac{K \times \text{length (m)}}{\text{serum creatinine (mg/dl)}}$$

where the value for K is 0.45 for full-term infants[45] and 0.35 for preterm infants.[46]

Urinary volume

It is usual for every normal neonate, regardless of gestational age, to void some amount of urine, if not during delivery, which sometimes goes unrecognized, then, by 24 hours of age. Premature infants usually void more often and in larger volumes relative to body weight (ml/kg/h) and GFR when compared with infants born at term[5] (Figure 21.5). For instance, in the first days following birth, the very small preterm infant will normally excrete about 10% of the volume of water filtered by the glomerulus when compared with 3% in the full-term infant and only 1% in the adult. One explanation for this difference is that the preterm infant has more extracellular fluid to excrete following birth than does the full-term infant, whose additional time in utero permitted the extracelluar fluid volume to be reduced before birth. The only way for the normal adult kidney to excrete 10% of glomerular filtrate in the urine is after massive saline expansion of the extracellular fluid volume.

The typical pattern of urinary volume in the full-term infant includes one to four voidings over the first 48 hours of life, with each subsequent voiding being somewhat smaller in volume than the last and with a higher specific gravity or osmolarity. When fed, urine



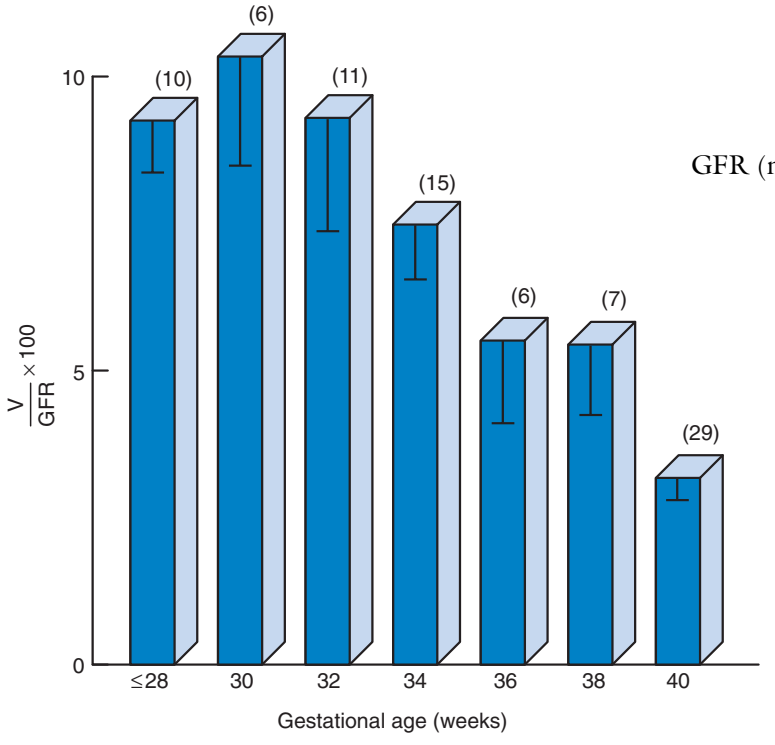


Figure 21.4 Plasma creatinine concentration measured at birth (upper panel) and during postnatal life (lower panel) compared with the conceptional age of infants. (From Arant,[43] with permission.)

production in the infant increases and the volume becomes larger and the urine less concentrated. Preterm infants, in contrast, void more frequently, with urine production usually being 3–7 ml/kg/hour during the first days of life. This urine is either isotonic or hypotonic to plasma despite a loss in body weight and reduction in extracellular fluid volume. The continued production of dilute urine depends on the volume of fluids provided to the infant and the insensible water losses experienced. Both premature and full-term infants are capable of concentrating their urines to a specific gravity >1.020 or an osmolarity of 700 mOsm/kg[9] once extracellular fluid volume has been reduced sufficiently to stimulate the baroreceptor-mediated release of arginine vasopressin from the hypothalamus. Markers for the end of the postnatal diuresis in a normal infant, regardless of maturity, are a reduction in the frequency and volume of urine excreted, increase in urinary osmolarity, and stabilization of the infant's body weight. If parenteral

$$\text{GFR (ml/min/1.73 m}^2) = \frac{K \times \text{length (cm)}}{\text{serum creatinine (mg/dl)}}$$

Figure 21.5 Fractional excretion of water [urine flow rate/glomerular filtration rate (GFR)] compared with gestational age of infants on the first day of life. (From Arant,[5] with permission.)

fluid therapy is overly aggressive, the expanded extracellular fluid volume characteristic of the fetus will result in a continued natriuresis and diuresis in the neonate.[5] Infants born with urologic disease, such as renal dysplasia or obstructive uropathy, may become dehydrated and hemodynamically unstable, since the ability to conserve sodium and concentrate the urine is almost certainly impaired.

In general, clinicians are comfortable when urine volume is >1 ml/kg/h, which corresponds to the urine volume of ~1500 ml/24 h in the adult. Just as one would be satisfied with slightly less urine in the adult, less urine is also acceptable in the healthy neonate. Urinary volume should never be interpreted alone, and the specific gravity or osmolarity must be considered as well. In the normal patient, neonate, or adult, there is an inverse relationship between urinary volume and urinary concentration. When urine volume changes, up or down, without a reciprocal change in concentration, an abnormal urinary tract, kidneys, or collecting system should be suspected.

Tubular handling of sodium

Perhaps more confusing than any other function of the neonatal kidney is its handling of sodium (Na). In the earliest reported studies, mature and premature human neonates could not excrete an NaCl load as well as an adult.[47,48] When studies of preterm infants were performed in neonatal intensive care units, renal Na wasting was often observed even in the face of hyponatremia.[49] One would think, ordinarily, that functional immaturity would be characterized first by a limited capacity of the growing renal tubule to reabsorb the Na filtered by the glomerulus. With maturation, the tubule would be able to reabsorb more. For many years, studies in both human infants and animal models held to this notion that preterm infants could not conserve sodium and full-term infants could not excrete it. The provision of Na in parenteral fluids and diet for preterm infants was decided on this basis. Then, several clinical studies were done in which the preterm infants were allowed to undergo postnatal diuresis and graduated weight loss. These infants maintained Na balance quite appropriately and very much like the adult.[50,51] In addition, preterm infants weighing <1000 g were given no Na in their fluids and only enough water to prevent the extracellular fluid from becoming hypertonic. Despite a negative Na balance from urinary losses, these very preterm infants were able to maintain a normal plasma Na concentration for the first week of life. One cannot

separate the renal handling of Na from changes in effective arterial blood volume (EABV), i.e. the combined simultaneous effects of blood pressure and blood volume. When baroreceptors in the renal circulation perceive an increased EABV, whether from an increase in blood volume or blood pressure, the mature kidney responds by an increase in the renal excretion of Na and water, which is facilitated by the inhibition of the release of both renin and arginine vasopressin.[5]

One cannot completely evaluate kidney function in the newborn infant without calculating the fractional excretion of Na (FENa):

$$\text{FENa}(\%) = \frac{\dfrac{\text{urinary Na (mmol/L)} \times \text{serum creatinine (mg/dl)}}{\text{plasma Na (mmol/L)} \times \text{urine creatinine (mg/dl)}}}{} \times 100$$

The result is a reliable indicator of the overall renal tubular handling of Na. FENa is <1% in the normal adult but can rise with an increase in EABV, by tubular injury as with diuretics, obstruction or renal disease, or by any maneuver that increases the fractional excretion of water (*V*/GFR) such as fluid overload.[5] When the kidney is maximally conserving the circulating blood volume, as in hypovolemic shock, dehydration, or congestive heart failure, oliguria is usual, *V*/GFR is <1%, the urinary concentration is maximal, and the FENa is much less than 1%, often only 0.1%. This would be true even if the patient had a positive Na balance and were hypernatremic. The status of the EABV overrides any signaling from body fluid osmolarity. The renal tubular handling of Na is related directly to *V*/GFR rather than to the variations in the maturity of the infant or its kidney.[5,52]

Acid–base balance

Unless demand becomes overwhelming, the neonatal kidney is capable of reabsorbing bicarbonate filtered by the glomerulus and secreting hydrogen ions or protons in a normal or mature fashion (80 mEq/1.73 m^2/day).[53] Most of the acidemia measured in preterm infants can be accounted for by respiratory acidosis. The relative metabolic acidosis in the neonate is implied when arterial blood gas (ABG) measurement reports a significant base deficit, often calculated on the assumption that the hemoglobin is 12 g/dl, which is inappropriate in the neonate whose hemoglobin may be ≥18 g/dl. The normal plasma bicarbonate or serum total CO_2 in newborn infants is 13–17 mmol/L in preterm infants and 19–21 mmol/L in full-term infants.[54] If the measured or calculated bicarbonate in arterial blood is subtracted inappropriately from the 'normal' plasma bicarbonate of the adult (28–30 mmol/L), as done customarily in ABG reports, the neonate will always have a 'base deficit'. Moreover, a mild hyperchloremia (plasma chloride concentration 103–110 mmol/L) is usually observed in normal neonates. The increased EABV results in a decrease in reabsorption of nearly all substances presented to the proximal tubule: not just Na and chloride, but also bicarbonate. Once the infant's extracellular fluid excess has been reduced following birth, proximal tubular reabsorption increases, the renal threshold for bicarbonate increases, and the so-called metabolic acidosis disappears.

One should have very good basis for treating metabolic acidosis in the neonate, and more than an ABG report. When the metabolic acidosis proves real, a reduction in renal glomerular or tubular function should be considered along with tissue hypoxia, especially if the anion gap is abnormal. Metabolic acidosis is common in urologic diseases identified in neonates. Distal tubular injury from obstruction or infection impairs the ability of that part of the nephron to secrete hydrogen ions and potassium. The metabolic acidosis and hyperkalemia in such infants suggest a tubular unresponsiveness to aldosterone or pseudohypoaldosteronism.

Renal tubular acidosis is an uncommon condition in newborn infants and should be considered only after the infant has been shown to have a metabolic acidosis, i.e. arterial blood pH <7.35 and hyperchloremia, and the urinary anion gap is positive (urinary Na concentration + urinary potassium concentration > urinary chloride concentration). Most so-called renal tubular acidosis in infants is a complication of diarrheal disease with the intestinal loss of bicarbonate: the urine pH is always <6.0 in these patients and the urinary anion gap is negative.

Hypertension

The incidence of hypertension in the first year of life is unknown. It is probably <2% in healthy infants, although obviously higher in infants with genitourinary abnormalities. There is a reluctance by most healthcare providers to attempt to record blood pressure. First, there is the technical difficulty in taking the blood pressure correctly and under reproducible conditions. Most physicians do not maintain a complete assortment of cuff sizes in their offices and the

size of the cuff influences the blood pressure reading significantly. The smaller the cuff, the higher the blood pressure. For the most accurate reading, the width of the cuff should cover more than 50% of the length of the humerus when the blood pressure is recorded in the upper extremity. Even if the infant is calm or sleeping, the effect of feeding and positioning has been shown to elevate the blood pressure above normal. Secondly, very few clinicians know how to interpret the blood pressure readings in infants unless very high readings are obtained (>95th percentile for age, gender, and length).[18] Consequently, it is the practice even in some tertiary pediatric facilities not to routinely record blood pressures on patients <3 years old.

If an elevated blood pressure is noted, the possible causes in the first year of life are few in number.[55] The most common etiology is due to a complication of an umbilical artery catheter, either from a thrombus that forms on the tip of the catheter and embolizes into the renal artery, or from an aortic wall thrombus at or above the renal arteries that propagates to occlude one or both renal arteries. These complications became uncommon when care was taken to keep catheter tips below the renal artery ostia, but there is now a more widespread practice of high catheter placement, especially in very small babies. It is likely, therefore, that the incidence of hypertension will once again increase in this group of neonates. Relative renal ischemia or actual cortical necrosis will be associated with severe hypertension and heart failure. The second cause of hypertension in the first year of life is autosomal recessive polycystic kidney disease. In most cases, the cystic kidneys have been identified by fetal ultrasonography or confirmed when enlarged and irregularly shaped kidneys are detected by abdominal palpation. Neurofibromatosis is almost the only cause of renal artery stenosis in the first year of life that leads to hypertension. It is unusual to find hypertension as a consequence of most other developmental abnormalities of the urinary tract. Hypertension is observed sometimes in premature infants who have suffered from barotraumas and have bronchopulmonary dysplasia, especially if they are being treated with corticosteroids. Catecholamine-producing tissues, such as pheochromocytoma and neuroblastoma, are rare causes of hypertension in infants.

Fluid therapy in the neonate

The general principle of fluid therapy in neonates is to restrict the volume of fluid given each day to less than the recommended maintenance volume (~100 ml/kg/day) until the infant has lost 5–15% of birth weight gradually, usually during the first 3–5 days of life. Premature infants will lose proportionally more weight than full-term infants. Once postnatal body weight has become constant, the urine flow rate slowed, and the urine concentration increased, the normal infant up to 10 kg body weight should receive about 100 ml/kg/day of water either by mouth, or parenterally when oral intake is not recommended. This amount represents the sum of insensible water losses (sweat, respiration, and gastrointestinal losses), which are approximately 30 ml/kg/day, and urine volume, usually about 70 ml/kg/day. Larger patients require less fluid per kilogram body weight to maintain total body water normal because of a decreasing caloric expenditure: 50 ml/kg/day for each kilogram between 11 and 20 kg and 20 ml/kg for each kilogram over 20 kg. Any condition that alters either insensible water losses or urine production must prompt a change in the volume of fluids administered; otherwise, dehydration or fluid overload is risked. After the immediate newborn period, infants will not tolerate long intervals of fluid deprivation without exhibiting signs of dehydration. Preoperatively, parenteral fluid therapy should be instituted when oral intake is discontinued.

There is only a very rare indication in pediatrics for using water or dextrose in water alone for parenteral fluid therapy. This is especially true in infants in whom water intoxication, hyponatremia, cerebral edema, and nervous system injury quickly follow the inappropriate administration of water without electrolytes. The exception will be the neonate whose insensible water losses in the first days of life only are replaced with 5–10% dextrose in water. Central diabetes insipidus is the only other clinical condition that calls for the administration of water without more electrolytes than needed to maintain the patient. To the calculated volume of water necessary for the infant or child, 1–3 mmol/kg/day of sodium, potassium, and chloride should be added.[56] This quantity of electrolytes is required for an expanding extracellular matrix and cellular proliferation to facilitate rapid somatic growth. The faster the rate of growth, the more electrolyte is needed. Recent controversy has included the notion that maintenance parenteral fluid therapy in hospitalized children should be only normal saline to prevent the occurrence and risks of acute hyponatremia. This argument has no merit for patients who are not at risk of developing syndrome of inappropriate antidiuretic hormone (SIADH) or

renal salt wasting. Calories must be provided daily to the infant or child. One cannot rely on a 5% dextrose solution, which, at best, affords only 20 kcal/kg/day when at least 65 kcal/kg/day is required to avoid catabolism in the patient. For the patient not expected to take oral feedings for more than 24 hours, consideration should be given to peripheral alimentation with up to 12.5% dextrose, essential amino acids (1 g/kg/day) and intralipid solution (1–3 g/kg/day).[57]

Summary

The greatest obstacle to understanding neonatal kidney function is not knowing which reported observation is or has remained valid. Without criticism, many statements are made and referenced in review articles and textbooks that perpetuate myths of so-called clinical experience and physiologic study. When one understands the normal physiologic responses of the adult or mature kidney, then a nearly complete appreciation of the fetal and neonatal kidney is within reach. The neonatal kidney functions qualitatively like the adult kidney, and its limitations come when unusual demands are made on it by stress, disease, or treatment.

Key Points

- A normal preterm infant may lose up to 25% of its birth weight and 14 mmol/kg of sodium during the first week of life and maintain serum sodium concentrations within the normal range.
- Angiotensin II is an important growth factor in the kidney and has an important role in regulating renal vascular resistance during development.
- Glomerular filtration rate remains relatively low in newborn infants until nephrogenesis is completed between 34–36 weeks after conception.
- Serum creatinine concentration at birth in the normal infant is nearly identical to the mother's serum creatinine concentration and in those born ≥34 weeks gestation is reduced by 50% by the end of the first week of life.
- All normal newborn infants are capable of concentrating their urines to a specific gravity >1.020 or osmolality >700 mOsm/L.
- Urinary volume is only a qualitative estimate of overall renal function and may be misleading in the presence of obstructive renal injury

Cystic kidney disease

22

Larry Greenbaum

Introduction

Cyst formation is seen in a variety of kidney diseases (Table 22.1). Many of these diseases are genetically inherited, and many are associated with extrarenal manifestations. They are generally relatively rare diseases, although a few are common enough to cause considerable pediatric morbidity and mortality. Autosomal dominant polycystic kidney disease (ADPKD) is actually one of the most common human genetic diseases, but its manifestations are usually fairly subtle in pediatric patients. It does cause considerable morbidity for adults, and it is likely that future therapy of this disease will focus on the pediatric patient.

Table 22.1 Cystic kidney diseases

Polycystic kidney disease:
■ Autosomal recessive polycystic kidney disease
■ Autosomal dominant polycystic kidney disease
Cysts of the medulla:
■ Juvenile nephronophthisis
■ Medullary cystic kidney disease
■ Medullary sponge kidney
Glomerulocystic kidney disease:
■ Sporadic glomerulocystic kidney disease
■ Familial hypoplastic glomerulocystic kidney disease
■ Autosomal dominant glomerulocystic kidney disease
Multicystic dysplastic kidney
Simple renal cysts
Multilocular cysts
Acquired cystic kidney disease
Syndromes with cystic kidneys:
■ Tuberous sclerosis
■ Meckel's syndrome
■ Von-Hippel–Lindau disease

The last decade has witnessed considerable advances in our understanding of cystic kidney diseases. The defective gene or genes have been cloned in a number of these diseases, and this has led to increased understanding of pathogenesis and clarified some important clinical issues. Such genetic studies have also provided opportunities for improved prenatal and postnatal diagnosis. Increased awareness and understanding of ADPKD has been associated with increased evaluation of asymptomatic children with ADPKD. In the long term, this has the potential of identifying a group that may benefit from early medical intervention. In the short term, this has created patient anxiety and diagnostic questions that are more related to medical insurance than patient care.

Identification of genes and proteins that are defective in the inherited cystic diseases has led to the discovery that most of these proteins are expressed in the primary cilium of renal epithelial cells.[1,2] This suggests that there may be a common pathway for cyst formation, potentially related to the role of primary cilia in signal transduction.[3,4]

Autosomal recessive polycystic kidney disease

The incidence of autosomal recessive polycystic kidney disease (ARPKD) has been estimated to be from 1 in 6000 to 1 in 55 000.[5,6] Since ADPKD can present in infancy and ARPKD can present in young adults, the designation ARPKD is more precise than the term 'infantile polycystic kidney disease.' Both the liver and kidneys are affected in ARPKD, with significant variability in severity between patients. Clinically, the prognosis for patients with ARPKD continues to improve.

Genetics

ARPKD is a classic recessively inherited disorder, with unaffected heterozygote parents and a 25% risk

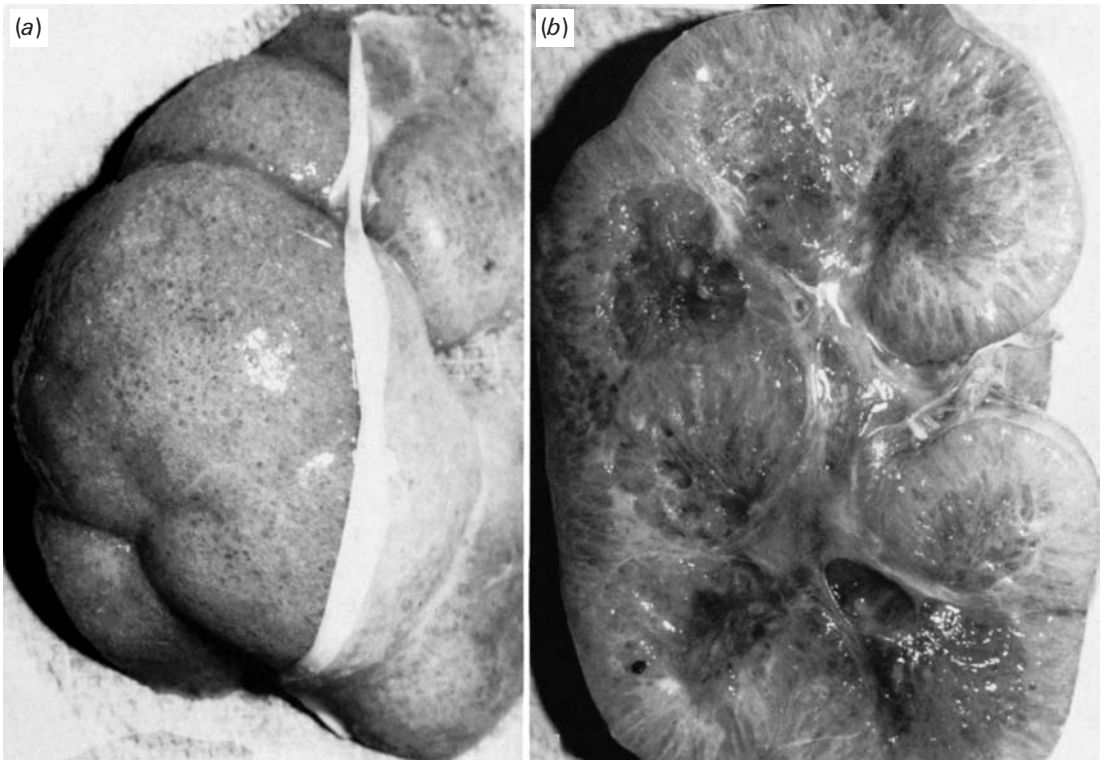

Figure 22.1 (*a*) Subcapsular surface of an autosomal recessive polycystic kidney from a neonate. Innumerable small cysts can be seen beneath the capsule. (*b*) Cross-section of the same kidney. The radial arrangement of the dilated ducts can be seen.

of an affected child in subsequent pregnancies. All cases of ARPKD are due to a mutation in the polycystic kidney and hepatic disease 1 (*PKHD1*) gene, which encodes the protein fibrocystin (also called polyductin).[7,8]

There is a correlation between the type of mutation and the clinical presentation. Infants with two truncating mutations typically die as neonates, whereas the clinical presentation varies in children with at least one missense mutation.[9,10] In general, the severity of ARPKD is similar among children within the same family, but there are examples of families where siblings have very different clinical manifestations.[10–13]

Pathology

The kidneys are enlarged bilaterally. This enlargement is usually fairly symmetrical, and the kidneys retain their reniform shape. Careful examination of the kidney capsule will often reveal opalescent dots, which are due to the termini of dilated collecting ducts below the kidney capsule (Figure 22.1). Grossly, the kidneys have a spongy appearance because of the cystic dilations of the collecting ducts.[14] Large cysts are unusual in infancy, although there is a gradual increase in cyst size over time.[15] The microscopic appearance is dominated by the dilated collecting ducts, which are perpendicular to the kidney surface (Figure 22.2). The cysts are lined with a normal-appearing single layer of cuboidal or columnar epithelium.[14] The glomeruli often appear normal in newborns. Over time there is increased interstitial fibrosis and glomerular sclerosis.

These patients have the typical features of congenital hepatic fibrosis.[16] There is proliferation and dilation of bile ducts and fibrosis of portal tracts. The distal portal veins are small, providing a microscopic explanation for the presence of portal hypertension. The absence of hepatocyte destruction correlates with the preservation of liver function.[17]

Clinical features

There is significant variability in the clinical features of ARPKD (Table 22.2). The majority of patients present during the first year of life, with a significant percentage presenting during the first month of life.[15,18–20] The most severely affected neonates can have some degree of Potter's syndrome due to oligohydramnios. Along with abnormal facies and joint

deformities, these children have respiratory compromise due to pulmonary hypoplasia. Volume overload from renal failure and poor diaphragm function secondary to the enlarged kidneys can also impair respiratory function. Respiratory failure is thus fairly common in neonates.[15,18–20] The importance of the mass effect of the enlarged kidneys has been confirmed by demonstrating improvement in respiratory function following unilateral nephrectomy.[21] Pneumothoraces are probably related to the hypoplasia and the high ventilatory settings that these infants require. Death due to respiratory failure can occur in the first few days of life.[18]

The kidneys in ARPKD are typically large at birth and often increase in size. This causes abdominal distention on physical examination, but also has additional important secondary consequences. By limiting diaphragm mobility, respiratory function is compromised, adding to the problems described above. In addition, the enlarged kidneys may impair gastric feeding[21] and patient mobility. It is important to note, however, that the kidney size can become less impressive over time in some patients, especially those that are receiving chronic dialysis.[15,22]

Chronic renal failure and, ultimately, end-stage renal disease (ESRD) is the usual outcome in ARPKD. Kidney failure may be present at birth,[15,20] although it more typically develops gradually, with most children who survive the neonatal period not progressing to ESRD until later in childhood or even as young adults.[22,23] Many patients have some improvement in renal function during the first year of life, followed by a period of stabilization and subsequent decline.[24,25] This is probably secondary to the normal maturation of kidney function. More aggressive therapy in the newborn period might theoretically select for patients with more severe renal involvement, although neonatal presentation is not necessarily a marker for earlier progression to ESRD.[22]

Chronic renal failure, especially untreated, is a potential cause of growth retardation. In addition, poor food intake, both due to renal failure and abdominal distention, may cause malnutrition. Not surprisingly, growth retardation is quite common in ARPKD,[15,26] and some children have severe growth retardation without a clear etiology.[22]

Hypertension is very common, probably due to fluid overload. The role of kidney renin production is not clear, with two studies failing to demonstrate increased renin or aldosterone levels.[18,22] Anywhere from 65–78% of patients require antihypertensive therapy.[6,18,20,22,25] The hypertension can be quite severe, causing severe morbidity[27] and even death.[18,22] Hypertension gradually diminishes in some children, and this may permit weaning of antihypertensive medications.[22]

There is an increased incidence of urinary tract infections;[6,20,28] this may be related to vesicoureteral reflux (VUR) and catheterization,[29] and is more common in girls.[26,28] However, pyuria is often present in the

absence of infection;[15] it appears to be less common in older children.[22] Proteinuria may be detected, often intermittently,[20] but it is not of sufficient magnitude to cause clinical problems. Gross hematuria is quite uncommon, but has been reported.[22]

Patients can have the typical electrolyte disturbances associated with renal failure, such as hyperkalemia and hyperphosphatemia. Acidosis develops with significant renal failure, but may be present earlier due to impairment in tubular acid excretion.[22,30] Patients almost always have a decreased ability to concentrate their urine,[20,22,30] and thus are at risk for dehydration and nocturnal enuresis. There is an increased risk of hyponatremia, which, when it occurs, is most common in infants.[18,28]

Portal hypertension due to congenital hepatic fibrosis leads to a number of complications. The liver may be enlarged and spider nevi are sometimes visible.[20,22,26,29,31] Splenomegaly was present in 47% of patients over 3 months of age in one series,[18] and this increased to 60% in children over 1 year of age.[29] This can be associated with anemia and thrombocytopenia.[29,31] Esophageal varices can lead to problems with hematemesis[31,32] and variceal rupture can be fatal.[18,20,29] Dilated biliary ducts predispose children with ARPKD to develop cholangitis.[28,31] This can occur in the neonatal period, and it has been fatal in some children.[20] Hepatocyte damage does not occur and synthetic function remains normal,[31,32] although mild abnormalities in liver enzymes are occasionally detected.[20,26]

Some patients initially have predominant liver involvement,[6,31] with kidney abnormalities discovered as an incidental radiographic finding. In fact, there are some adults diagnosed with congenital hepatic fibrosis or Caroli's disease who have mutations in the *PKHD1* gene.[33] Other children have both severe liver and kidney disease at an early age.[22] The hypothesis that severe liver disease predicts minimal renal involvement[34] is no longer accepted.[16]

It is possible that additional clinical features of ARPKD may be discovered as patients survive further into adulthood. For example, intracranial aneurysms were described in a 31-year-old patient with ARPKD.[35] Although only a case report, this is especially intriguing given the presence of intracranial aneurysms in ADPKD.[36]

Radiologic features

An intravenous pyelogram (IVP) shows enlarged kidneys with a delayed nephrogram (Figure 22.3).[37,38] Radial streaks due to contrast in the dilated collecting ducts are usually present in infancy, but may not be visible in older children.[19] Because of concerns regarding intravenous contrast, a renal ultrasound is now the usual front-line diagnostic test. Ultrasound shows enlarged kidneys with increased echogenicity and poor corticomedullary differentiation (Figure 22.4);[39,40] a hypoechoic rim is often visible.[41] Older

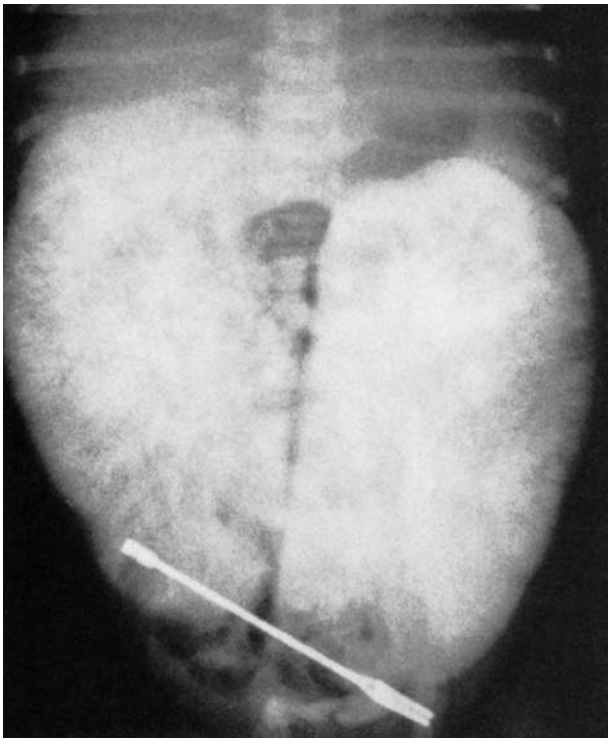

Figure 22.3 IVP from a 2-day-old girl with ARPKD. Note the sunray appearance of the contrast material and the enormous renal size.

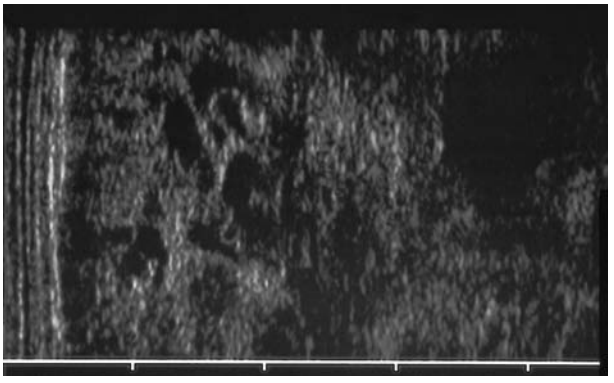

Figure 22.5 High-resolution renal ultrasound of the same patient shown in Figure 22.4. With high resolution, cysts are seen and the hypoechoic rim is still visible. (Courtesy of Dr J Sty, Children's Hospital of Wisconsin.)

children have increased medullary echogenicity, which may resemble nephrocalcinosis.[22] Multiple small cysts may be visible by ultrasound,[22,40] but this is quite variable (Figure 22.5). Macrocysts are sometimes visible in older children.[35,39,40,42]

Ultrasound detects liver abnormalities in approximately 50% of patients.[22,28] It is often possible to detect dilations of the peripheral intrahepatic biliary ducts and the principal biliary duct. There may also be evidence of portal hypertension.[22]

Diagnosis

A large percentage of children are now diagnosed from an abnormal prenatal ultrasound.[28] The presence of bilaterally enlarged kidneys during the first few years of life is suggestive of ARPKD. The radiologic features, as detailed above, can be helpful, but are not always conclusive. This is especially true in older patients with ARPKD, since cysts may have enlarged and thus resemble those seen in ADPKD.[35] It is important to investigate the family history; the presence of a sibling with ARPKD is obviously highly suggestive. Consideration must be given to an early presentation of ADPKD, and therefore it is now common to augment the family history with renal ultrasounds of the parents, and possibly the grandparents if the parents are young, to rule out this possibility. In one study, 6.7% of the patients with neonatally lethal polycystic kidney disease had ADPKD.[20] For inconclusive cases, histologic examination of the liver is useful. Congenital hepatic fibrosis is always present in ARPKD and is extremely rare in ADPKD.[43,44] Liver ultrasound may also demonstrate hepatic disease.[22] Kidney biopsy is rarely performed because of concerns regarding the safety of the procedure in these children. In the histologic evaluation of the kidney, the absence of glomerular cysts supports a diagnosis of ARPKD.

Genetic diagnosis, which is not yet commercially available, is challenging because the *PKDH1* gene is extremely large and complex, and the known mutations are quite heterogeneous.[10,33] Mutations are more likely to be detected in children with severe ARPKD than in children with moderate disease.[10,33] Linkage analysis improves the diagnostic yield if there is an affected sibling.[45]

Nephroblastomatosis and bilateral Wilms' tumor are part of the differential diagnosis of bilaterally enlarged kidneys. Transient nephromegaly of the newborn can be confused with ARPKD,[46] but this resolves relatively quickly. A variety of other diseases with renal involvement can also have hepatic manifestations. These include Meckel's syndrome,[47] juvenile nephronophthisis,[48] Ivemark's syndrome,[49] Jeune's syndrome,[50] COACH syndrome,[51] and Bardet–Biedl syndrome.[52]

Prenatal diagnosis

Prenatal ultrasound often detects abnormalities in a fetus with ARPKD.[6,53–58] The kidneys may be hyperechoic[55] and increased in size.[56–58] Serial ultrasound showing inappropriate increases in kidney length improves diagnostic reliability.[54] In addition, some fetuses have oligohydramnios. However, a precise diagnosis is often impossible prenatally given the limits of current imaging and alternative diagnostic possibilities. Naturally, in a family with a previous child who has ARPKD, the clinical likelihood of this diagnosis is increased. Unfortunately, there have been cases of both false-positive and false-negative diagnoses.[55,59] False positives are especially likely in a fetus without a family history of ARPKD or if oligohydramnios is not present.[55] Conversely, in a family at risk, a normal prenatal ultrasound, especially before the third trimester, should not be used to predict an unaffected child.[13,58–60] Fetal magnetic resonance imaginary (MRI) has also been used to diagnose ARPKD.[61]

As stated previously, mutation screening is difficult, not commercially available, and currently not close to 100% sensitive.[10,33] Linkage analysis can determine if a fetus has ARPKD in families with a previously affected child.[45] This analysis requires preservation of DNA from the previous child. Such analysis is currently not commercially available, but can be performed at research laboratories in Europe and the

United States.[62] The clinical course of a previously affected child does not always predict the severity of the ARPKD in a subsequent child.[13,18] Parents clearly need genetic counseling regarding this possibility. Supplementing linkage analysis with prenatal imaging studies could theoretically aid in this discussion, but it is especially difficult to make outcome predictions based on the fetal ultrasound.[13]

Treatment

The initial management of respiratory distress is quite challenging. In the past, many of these children were presumed to have pulmonary hypoplasia, and thus therapy was limited. It is now clear that other factors contribute to the respiratory insufficiency. Both unilateral and bilateral nephrectomies, by decreasing the effect of abdominal distention, have been successfully used to improve respiratory function and allow children to wean from respiratory support.[21,63] Although providing a less dramatic decrease in abdominal distention, unilateral nephrectomy can be done without forcing the patient to undergo dialysis.[21] It is important to evaluate relative renal function before proceeding with a unilateral nephrectomy, lest the remaining kidney have limited function. Bilateral nephrectomies require that a peritoneal dialysis catheter be placed simultaneously; it is therefore recommended that the kidneys be removed extraperitoneally, with meticulous attention to the peritoneal membrane.[63]

Reversible causes of respiratory insufficiency, such as volume overload, persistent fetal circulation, hyaline membrane disease, infection, and pneumothoraces, should be treated before concluding that a patient has irreversible pulmonary failure. The use of more aggressive perinatal support strategies such as surfactant, high-frequency oscillatory ventilation,[21] extracorporeal membrane oxygenation (ECMO), dialysis, and hemofiltration may also decrease the mortality from respiratory failure.

The massively enlarged kidneys create a variety of problems beyond respiratory distress. Both unilateral and bilateral nephrectomies can have other benefits, such as improved tolerance of feedings[21] and increased activity in older children. Left nephrectomy, assuming equivalent renal size, may have more benefits for gastric function than a right nephrectomy.[21]

Hypertension should be aggressively treated, given that uncontrolled hypertension has been associated with severe complications and even death.[18] Hypertension frequently requires multiple medications,[28] and is often difficult to control,[6] leading to bilateral nephrectomy and the initiation of peritoneal dialysis in some children.[29] Interestingly, hypertension may sometimes lessen as the patient ages, allowing successful weaning of antihypertensive medications.[25,29]

Chronic renal failure and ESRD are managed using the usual strategies. Patients are treated for electrolyte problems, anemia, and renal osteodystrophy. Tube feedings and growth hormone are often necessary to manage failure to thrive. Dialysis and, ultimately, transplantation are needed when the patient reaches ESRD. Peritoneal dialysis is the preferred modality, but hemodialysis can be utilized if necessary. Both peritoneal dialysis and transplantation may require prior nephrectomies to create sufficient abdominal space.

Complications of portal hypertension need to be addressed.[64] Esophageal varices may require sclerotherapy or placement of a portacaval shunt,[31,65] with one patient receiving a shunt as early as 2 years of age.[18] Cholangitis needs to be aggressively treated with antibiotics. Splenectomy has been performed in children with intractable hypersplenism that causes anemia and thrombocytopenia.[29] Liver transplantation is occasionally necessary.[28]

Prognosis

ARPKD is associated with considerable morbidity and mortality. Improved therapy in the newborn intensive care unit and better treatment for chronic renal failure is continually changing the long-term prognosis. Nevertheless, patients continue to die, with much of the mortality occurring in the first year of life, especially during the first month.[18,20,22,28] Respiratory failure and sepsis are currently the most common causes of death.[28] Neonatal ventilation is a strong predictor of mortality and the early development of chronic renal failure.[28] Children who survive beyond the first month had a 5-year survival of 87% in a report of a North American registry.[28]

There is clearly significant long-term morbidity in these patients as a result of chronic renal failure, systemic hypertension, and portal hypertension. However, patients are continuing to benefit from improvements in surgical and medical management.

Autosomal dominant polycystic kidney disease

ADPKD, with an incidence of 1:500 to 1:1000, is the most common inherited kidney disease. Although kidney involvement is the major feature for most

patients, there are protean extrarenal manifestations, including the potentially life-threatening possibility of a ruptured intracranial aneurysm. Severity varies greatly between patients and symptoms tend to develop over time. Fortunately, most children are asymptomatic; even middle-age adults may be unaware of their diagnosis. There are, however, children with severe and occasionally fatal disease. This underscores the importance of avoiding the term 'adult' PKD.

An increasing percentage of children with ADPKD are diagnosed from a positive family history or because of an incidental finding during an imaging study. This has caused a marked shift in the pediatric patient population, with many patients having no symptoms and requiring very limited intervention.

Genetics

ADPKD is a genetically heterogeneous condition; disease occurs owing to mutations in one of at least two separate genetic loci (Table 22.3). Patients with a mutation of the *PKD1* gene,[66] which is located on chromosome 16, account for approximately 85% of cases. Most remaining cases are due to a mutation in the *PKD2* gene on chromosome 4.[67] The presence of a third locus (*PKD3*) is inferred based on studies showing an absence of genetic linkage to either *PKD1* or *PKD2* in some families with ADPKD,[68–70] although the evidence for a third locus has been questioned.[71]

Table 22.3 Multiple gene defects that cause ADPKD

Gene	Chromosome location	Protein
PKD1	16p	Polycystin
PKD2	4q	Polycystin-2
PKD3	Unknown	Unknown

PKD1 encodes for a protein called polycystin, which is a transmembrane protein with multiple extracellular domains.[72] The *PKD2* gene product, polycystin-2, is also a transmembrane protein and has moderate homology to polycystin.[67] Polycystin and polycystin-2 interact with each other, and are localized within primary cilia.[73–75]

The variable development of cyst formation in ADPKD appears to be related to the need for a second inactivating mutation. The kidney cells of patients with the *PKD1* mutation initially have one normal gene for polycystin and one defective gene. Cyst formation occurs when there is a second somatic mutation that inactivates the good gene. This produces a cell that does not produce any normal polycystin. Additional cysts are due to a second mutation in other cells.[76,77] A similar mechanism takes place in patients with *PKD2*.[78,79] This helps to explain why cysts appear fairly randomly and increase in number over time.

There is a great deal of variability in the severity of ADPKD, some of which is based on the specific gene affected. Patients with PKD2 have less severe symptoms, including later mean age for the development of ESRD and a decreased incidence of hypertension, urinary tract infections (UTIs), and hematuria.[80] In one study, the median age of death or onset of ESRD was 53 and 69 years in patients with PKD1 and PKD2, respectively.[80] There is also evidence that the disease severity is influenced by the specific mutation (allelic heterogeneity) in the *PKD1* or *PKD2* genes.[81–83] Additional sources of variability may involve environmental factors and genetic differences at other loci.[84–86] For example, polymorphisms in the angiotensin-converting enzyme (ACE) gene modify renal disease severity in patients with PKD1.[87]

In cases of neonatal ADPKD, the affected parents have not had early-onset disease.[20,88,89] However, there appears to be an increased likelihood of early disease in affected siblings[20,88,90,91] and other members of the same kindred.[89] Early-onset disease may be more likely in families with mutations in *PKD1*.[92]

Pathology

The kidneys are typically enlarged and have random cysts, which can originate from any portion of the nephron (Figure 22.6). Except for cysts, the renal architecture is initially normal, although as the disease progresses fibrosis and glomerulosclerosis gradually increase.

Clinical features

Most children with ADPKD are asymptomatic, and increasing numbers of these patients are diagnosed based on a positive family history followed by a screening computed tomography (CT) scan or ultrasound. Others are diagnosed after kidney cysts are incidentally noted on an imaging study, including prenatal ultrasound.

Although children are often asymptomatic, there are reports of severe disease, including neonatally lethal

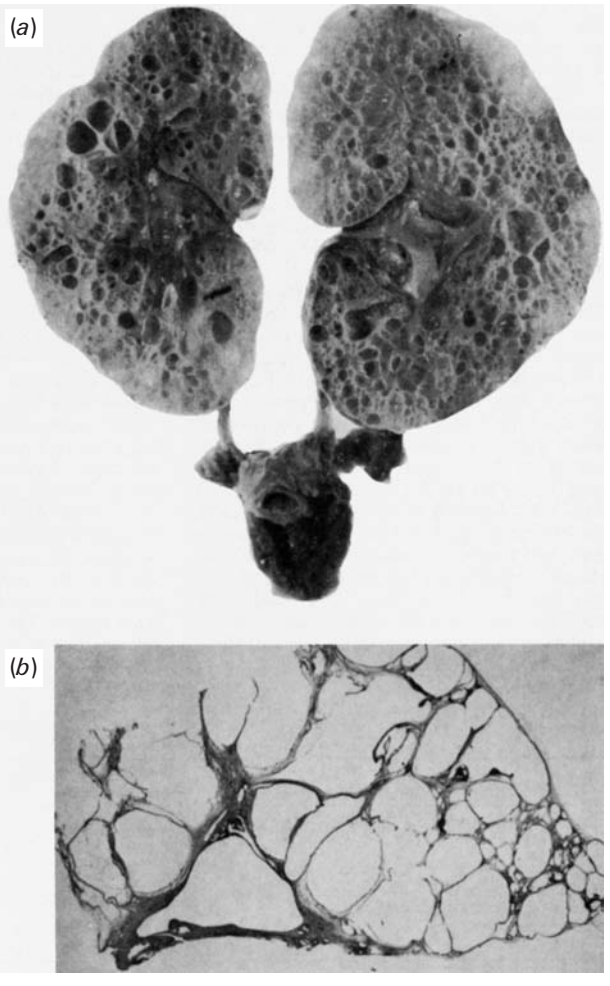

Figure 22.6 (*a*) Example of 'adult' polycystic kidney disease in a 3-month-old infant. Note the rounded cysts of varying size. (*b*) Low-power view of the same kidney. Foci of normal renal tissue are seen between the grossly dilated tubules. (Reproduced with permission from Blyth and Ockenden.[34])

disease.[20,88,93] Neonatal mortality is usually a result of respiratory failure and is associated with massively enlarged kidneys.[20,90,93] Most neonates diagnosed on the basis of on an abnormal prenatal ultrasound are asymptomatic. The majority of these children maintain normal renal function, but some will reach ESRD during childhood.[22,92–94] Maternal inheritance may be a risk factor for neonatal presentation.[95]

Most children with symptomatic ADPKD have a more subtle presenting complaint, typically in late childhood or adolescence.[20,22] Hematuria is quite common in adults with ADPKD[96] and can manifest in childhood.[20,22,97,98] Other presenting symptoms include hypertension, frequency, abdominal or flank pain, abdominal mass, UTI, and proteinuria (Table 22.4).[20,22,98,99] The majority of patients who are

Table 22.4 Presenting complaints in symptomatic children with ADPKD[a]

Symptom	Gagnadoux et al[22]	Fick et al[99]	Kääriäinen et al[91]
Hematuria	3	2	2
Abdominal pain	3	1	1
Hypertension	3	1	0
Renal mass	1	1	0
Frequency	0	2	0
UTI	0	1	1
Proteinuria	0	0	1

[a] This table excludes patients with severe neonatal disease.

symptomatic during childhood do not have renal insufficiency as young adults,[22] but they may be at a higher risk for early kidney failure.[98]

The presence of symptoms in children correlates with the number of cysts. Children with more than 10 cysts have an increased incidence of flank or back pain, palpable kidneys, and hypertension.[99] Such children also have more complaints of palpitations and urinary frequency than their unaffected siblings.[99]

Hypertension and resultant end-organ damage occurs in children with ADPKD. When a group of mostly asymptomatic children were screened, 13% had hypertension (vs 0% of controls) and the hypertensive patients had left ventricular hypertrophy.[100] A smaller study using ambulatory blood pressure monitoring found no evidence of hypertension in patients <15 years, but there was an increase in left ventricular mass.[101] In addition, patients between 15 and 25 years had significant increases in blood pressure and ventricular mass.[101] Another study found hypertension at clinical presentation in 22% of children.[95] Not surprisingly, hypertension is more common in children who are symptomatic in the neonatal period.[20] The renin–angiotensin system is implicated in hypertensive adults with ADPKD and normal renal function,[102] although this mechanism has not been studied in children.

Some children with mild ADPKD have a subtle defect in urinary concentrating ability,[22] and this is more common in children with more than 10 cysts.[99] Children with more than 10 cysts also have an increased incidence of proteinuria.[103] Kidney stones, often presenting as acute flank pain, are increased in adults,[104] but are infrequent in children.

Kidney infections are more common in patients with ADPKD, and complications may include

Table 22.5 Extrarenal symptoms in ADPKD

Mitral valve prolapse
Hypertension
Extrarenal cysts:

Cholangiocarcinoma
Congenital hepatic fibrosis

perinephric abscess, septicemia, and death;[105] there may be an increased risk of VUR.[106] Cyst infection is especially troublesome, since the urine culture may be negative and not all antibiotics achieve therapeutic levels in the cyst fluid.[105]

There are a large number of possible extrarenal manifestations in adults with ADPKD (Table 22.5). Extrarenal involvement is less common in childhood. Mitral valve prolapse (MVP) is found in 26% of adults with ADPKD.[107] Among a group of children, 12% had MVP (vs 3% of controls) and the incidence increased with age.[100] Inguinal hernias are substantially increased in both children[98,99] and adults.[108,109]

Liver cysts are the most common extrarenal manifestation in adults with ADPKD, with the prevalence increasing with age.[110,111] Women tend to have more and larger cysts[112] and pregnancy is an additional risk factor.[111] Some adults experience abdominal fullness and pain, but cysts almost never impair liver function or cause portal hypertension,[110,112] except in extreme cases.[113] Infected liver cysts present with pain, fever, and leukocytosis.[114] Liver cysts are rare in children.[99,115] Liver enlargement[20] has occasionally been described in children. A few patients with ADPKD have congenital hepatic fibrosis;[43,44,116] but this liver involvement is usually restricted to one member of the family and thus does not appear to be related to a unique ADPKD gene defect.

Pancreatic cysts are present in only 9% of patients over 30 years of age,[117] and almost never cause complications;[118] they are extremely unusual in children.[115] The claim that ovarian cysts are increased in ADPKD has been questioned.[119] The remaining cystic complications are quite rare.[120]

Ruptured intracranial aneurysms are a significant cause of mortality in adults with ADPKD.[121] In one study, the mean age of bleeding was 39.5 years, but 10% of patients were <20 years.[122] There are reports of young children with a subarachnoid hemorrhage,[20] a bleeding arteriovenous malformation (AVM),[123] and ruptured intracranial aneurysms.[124,125] Aneurysms cluster in families,[126–128] and thus a positive family history for intracranial hemorrhage or aneurysm is an important risk factor.

Gender differences in ADPKD include the predisposition to liver cysts in women. The rate of progression to kidney failure is faster in adult males with either PKD1[129] or PKD2.[80] No gender differences among children have been reported.[99]

Radiologic features

Ultrasound (Figure 22.7) and CT scan (Figure 22.8) are useful for detecting the macroscopic cysts of

Figure 22.7 Ultrasound of an infant with severe ADPKD. The kidneys are enlarged owing to multiple cysts. (Courtesy of Dr J Sty, Children's Hospital of Wisconsin.)

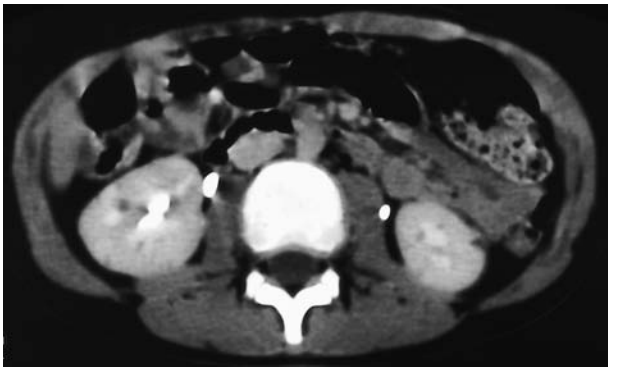

Figure 22.8 CT scan of a child with ADPKD. Macroscopic cysts are readily visible. (Courtesy of Dr J Sty, Children's Hospital of Wisconsin.)

ADPKD. The number and size of cysts in children increase with age, and those children with more cysts have increased kidney size.[99] Increased renal echogenicity may be seen in some children.[40] Occasionally, children can have marked disease asymmetry, which can create diagnostic confusion.[130] Liver cysts are quite unusual in children.[99]

Diagnosis

Rare, early-onset ADPKD can sometimes be diagnosed by prenatal ultrasound,[88,89,116,131] although most cases are identified in the last 10 weeks of gestation. The kidneys are large, with increased echogenicity, and cannot easily be distinguished from the kidneys of children with ARPKD. Occasionally, macrocysts are identified.[116] Early diagnosis in a fetus with an affected parent is possible using DNA analysis.[132,133]

Even after birth it is often difficult to distinguish early-onset ADPKD from ARPKD. Radiologic studies of the kidneys are often inconclusive. Liver imaging or biopsy is useful because hepatic fibrosis is always present in ARPKD and extremely rare in ADPKD. Kidney pathology is also helpful, given the absence of glomerular cysts in ARPKD. The presence of a parent with ADPKD is the most useful diagnostic clue. Yet, many parents are unaware of their own disease,[22,92] and thus screening imaging studies of 'normal' parents are mandatory. Because of the possibility of a false-negative radiologic study, screening of the grandparents is sometimes useful, especially if the parents are <30 years old.

Diagnosis in asymptomatic or mildly symptomatic children is usually accomplished by renal ultrasound. The sensitivity and specificity of this approach increases with the child's age (Table 22.6). CT scan, although perhaps more sensitive than ultrasound,[135] is usually not a front-line approach because of the greater ease of ultrasound. Unilateral cysts may be the only initial finding in children with ADPKD,[22,99,124,130,136,137] and in the context of a positive family history even a single cyst is highly suggestive of disease.[134] Bilateral cysts are frequently found on later investigation.[99] For adults, given the increased incidence of benign solitary cysts, more stringent criteria are necessary to avoid false positives.[138]

Table 22.6 Sensitivity and specificity of ultrasound for detecting ADPKD in children

Age	Specificity (%)	Sensitivity (%)
3 months–5 years	89	62
5 years–10 years	100	82
10 years–15 years	100	86
15 years–17.5 years	100	67

This table summarizes the results of ultrasound screening in a group of children with PKD1 by linkage analysis. The presence of a single cyst was interpreted as a positive ultrasound. Table adapted from Gabow et al.[134]

The ability to screen patients for mutations in the *PKD1* or *PKD2* genes is currently commercially available, although false-negative results can occur. Identifying a mutation in a known affected family member is useful for proving that a negative result is a true negative.

The increasing ability to diagnose ADPKD raises some important issues. Unlike many other genetic diseases, the morbidity and mortality in ADPKD typically occurs in older adults and problems are fairly modest in many patients. Nevertheless, among a group of adults at risk for the disease, 97% would like to receive genetic testing.[139] There is also enthusiasm for genetic testing of offspring, with 89% selecting this option.[139] However, knowledge of the presence of this disease has little impact on reproductive decisions. Only 11% of patients do not have children because of the risk of passing the disease to offspring and even fewer (4%) would terminate a pregnancy for ADPKD.[139]

Screening and monitoring

Many children have a parent with ADPKD and therefore have a 50% risk of carrying the defective gene. Undiagnosed, asymptomatic patients may have significant abnormalities such as hypertension, proteinuria, bacteriuria, and an increased creatinine.[140] Certainly, at-risk children need periodic screening, with special attention to the blood pressure. A possible algorithm is presented in Figure 22.9. Screening ultrasounds are not recommended because of concerns regarding obtaining health insurance.[141] A more aggressive approach will be necessary if an effective early treatment for ADPKD becomes available.[142] Figure 22.9 also presents a basic approach to monitoring the child with a diagnosis of ADPKD, with the caveat that monitoring needs to be customized for the individual patient.

Treatment

Children with severe disease receive standard therapy for chronic renal insufficiency. This should include

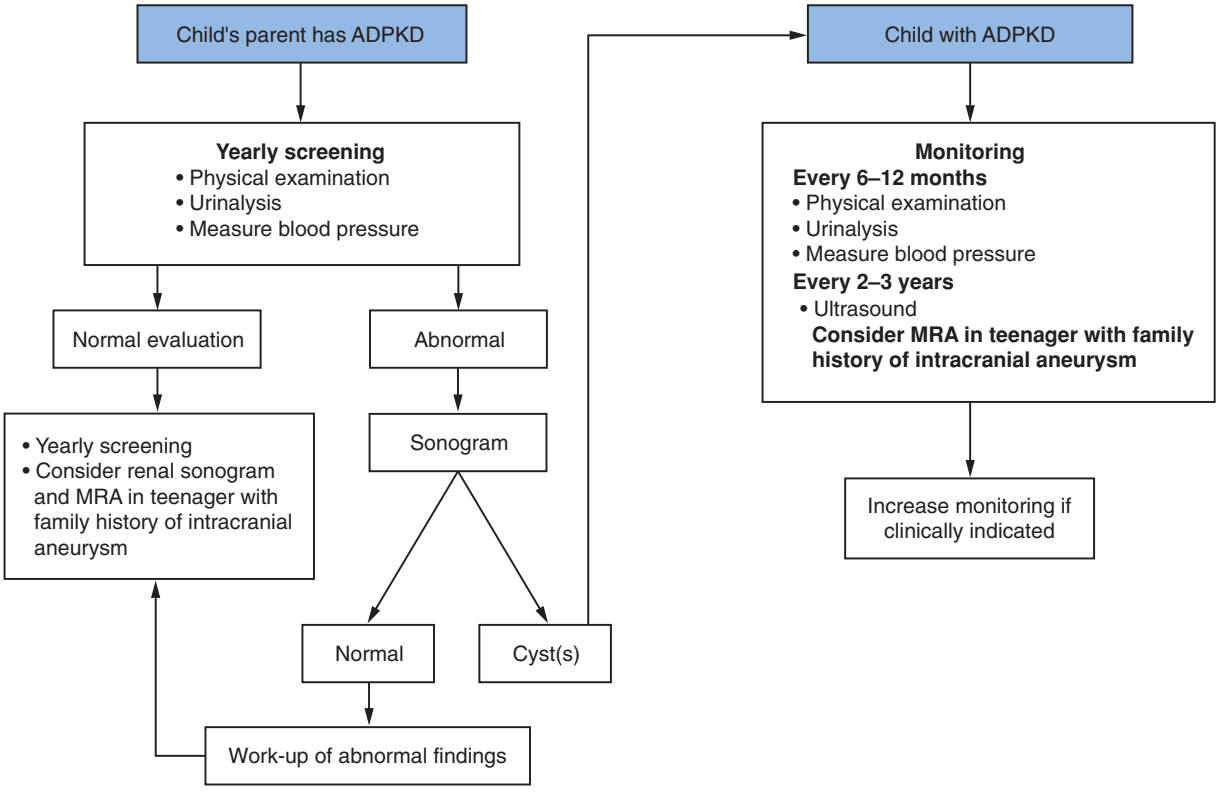

Figure 22.9 ADPKD: screening and monitoring of children. MRA, magnetic resonance angiography.

careful monitoring of nutrition and growth. In adults with moderate renal insufficiency, there was no benefit to protein restriction, although there was a marginal slowing in the rate of decline of the glomerular filtration rate (GFR) in patients with severe renal insufficiency.[143] Such an approach is not recommended in children because the benefits are minimal and there is potential for adverse effects on growth and development. A variety of other interventions to slow the progression of ADPKD have been tested in animal models, and a clinical trial of a vasopressin 2 receptor antagonist is currently underway in adults.[142]

Hypertension is fairly common in older children with ADPKD and should be treated. In adults with ADPKD, rigorous control of blood pressure was superior to standard control in reversing left ventricular hypertrophy.[144] There is not a consensus on the ideal class of antihypertensive agent to select for these patients. Despite the pathogenic role of the renin–angiotensin system[102] and the evidence that ACE inhibitors slow the progression of renal insufficiency in a variety of kidney diseases,[145,146] ACE inhibitors, when rigorously tested, do not slow the progression of chronic renal insufficiency in ADPKD.[146] ACE inhibitors do reverse left ventricular hypertrophy in hypertensive adults with ADPKD,[147] but there is a small risk of precipitating acute renal failure in patients with ADPKD, and thus they must be used cautiously.[148] Other agents, such as calcium channel blockers, have also been advocated.[149]

The goal of therapy is normalization of blood pressure using standard guidelines.[150] In adults with ADPKD, low targets for blood pressure may have a deleterious effect on renal function.[143]

Urinary tract infections should be treated promptly, with awareness for the increased risk of abscesses and septicemia. Cyst infection requires selection of an antibiotic that penetrates the cyst, such as trimethoprim–sulfamethoxazole[151] or ciprofloxacin;[152] occasionally, cyst aspiration may be necessary.[153] Patients with intractable pain from renal cysts can benefit from either cyst aspiration, surgical reduction, or thoracoscopic denervation.[154,155]

The possibility of a ruptured intracranial aneurysm is a frightening, albeit rare complication in pediatric patients. The advisability of screening patients is currently being debated. Magnetic resonance angiography (MRA) is a safe and sensitive approach for detecting an asymptomatic aneurysm.[126] However,

Table 22.7 Genetic heterogeneity of nephronophthisis (NPH)

Type	Chromosome locations	Gene mutated	Encoded protein	Clinical form
NPH type 1	2q13	*NPHP1*	Nephrocystin	Juvenile
NPH type 2	9q22	*NPHP2*	Inversin	Infantile
NPH type 3	3q22	*NPHP3*	Nephrocystin-3	Adolescent
NPH type 4	1p36	*NPHP4*	Nephrocystin-4	Juvenile

there is a need to balance the safety and efficacy of surgical intervention with the risk of aneurysm rupture. One decision analysis supported screening a 20-year-old patient with ADPKD,[156] although others have suggested a less aggressive approach.[157,158] Because of the familial predilection to aneurysm formation,[126,127] screening of older teenagers with a positive family history is a reasonable approach.[159] However, patient selection, timing, and frequency of screening continue to evolve.[160,161]

Prognosis

Most children with ADPKD will have minimal symptoms throughout childhood. The adult course of the disease is extremely variable.

There are currently limited data on the ultimate prognosis for patients diagnosed during childhood. This is especially true for patients with asymptomatic cysts; the impact of increased numbers of cysts on the risk of chronic renal failure is unknown. Children who are diagnosed after the neonatal period do not have a decrease in GFR, even in the subgroup with more cysts and symptoms.[99] In adults, the presence of the *PKD1* gene, younger age at diagnosis, male gender, hypertension, increased left ventricular mass, hepatic cysts in women, three or more pregnancies, gross hematuria, UTI in men, proteinuria, and renal volume are all independently associated with poor renal function.[129,162] In children, increased renal volume in early life or hypertension is associated with subsequent faster renal growth, a potential marker of a worse prognosis.[163] There seems to be a higher risk of early chronic renal failure when patients have more severe disease as children.[98]

Interestingly, many children diagnosed antenatally have normal renal function,[22] although follow-up is relatively limited. The cases diagnosed neonatally frequently have severe, often fatal, disease. These children are at risk for early chronic renal insufficiency and ESRD. However, others maintain normal renal function throughout childhood.[92]

Nephronophthisis

Nephronophthisis (NPH), also called 'juvenile nephronophthisis,' is one of the most common causes of chronic renal insufficiency in children.[164] NPH, which is recessively inherited, is often grouped with dominantly inherited medullary cystic disease because of an overlapping radiologic and histologic appearance. However, medullary cystic disease is genetically distinct, lacks extrarenal involvement, and usually presents in adulthood. We will therefore consider it separately later in this chapter.

Genetics

Mutations at four different loci may cause NPH (Table 22.7), and additional genetic heterogeneity is likely.[165] The majority of cases of NPH are due to mutations in the *NPHP1* gene.[166,167] Most patients with nephronophthisis type 1 are homozygous for a large deletion that affects the *NPHP1* gene.[166,168]

Pathology

Grossly the kidneys are often small and have a pale finely granular surface.[169,170] On light microscopy, there is diffuse interstitial fibrosis with a mononuclear cell infiltration.[169,171,172] Along with tubular atrophy, there is extreme thickening and lamination of the tubular basement membranes.[169,171] Electron microscopy confirms this thickening, and also shows splitting of the basement membrane.[169] In a child with a biopsy early in the course of the disease, tubular basement membrane thickening was the only histologic abnormality.[172] Cysts appear to originate from the distal convoluted tubules and collecting ducts.[171] The glomeruli may be normal or have periglomerular fibrosis with thickening of Bowman's capsule; glomerular obsolescence eventually develops.[169]

Clinical features

Polyuria and polydipsia are due to poor urinary concentrating ability, and this can lead to problems such

as dehydration, nocturia, and primary or secondary nocturnal enuresis.[169,173,174] Renal sodium wasting[169] leads to salt craving in some children.[173] The urinalysis is notable for the absence of abnormalities,[169,170,173] although low levels of proteinuria, usually tubular in origin,[174] are sometimes present. Glucosuria is also occasionally present.[174,175] Probably due to the polyuria and salt wasting, hypertension is unusual,[170,176] except in patients with NPH type 2. Symptoms of chronic renal failure, such as fatigue, anorexia, and growth retardation, are frequently present.[170,173,174,177] Symptoms of renal osteodystrophy may be the initial complaint.[177] Children with NPH have an anemia that is out of proportion to their degree of renal failure, and thus often have very low hematocrits and notable pallor.[170,173,174,177,178] The anemia appears to be due to decreased erythropoietin production.[179]

The majority of patients with NPH type 1 develop ESRD at a mean age of about 10–13 years.[169,180] The defect in urine concentrating ability can lead to severe dehydration and acute renal failure, which may accelerate the development of chronic renal failure.[180]

NPH type 2 is distinct from the other forms of NPH. Renal failure occurs in infancy, and the kidneys are large with widespread cysts.[181,182] Hypertension is more common than in the other forms of NPH. *NPHP2* gene defects may also lead to situs inversus in a minority of children.[182] The timing of ESRD is fairly similar in NPH type 1 and NPH type 4, whereas ESRD develops at about a mean age of 19 years in NPH type 3.[180,183]

Senior–Løken syndrome is the combination of NPH with tapetoretinal degeneration.[184,185] In the early-onset form, called congenital amaurosis of Leber, nystagmus is usually present, and there is an absent pupillary response to light. The retina is markedly abnormal on funduscopic examination; findings include arteriolar narrowing, pale optic disks, and granular pigmentation of the fundus.[186] Most patients are blind or severely visually impaired, and have a flat electroretinogram.[174] There is a late-onset form of Senior–Løken syndrome in which visual impairment develops during childhood. Moreover, patients with a defect in the *NPHP1* gene may have ocular findings, including areas of retinal atrophy with flat or low-voltage electroretinograms. However, these patients are usually asymptomatic, and probably should not be considered to have Senior–Løken syndrome.[176,187,188] Senior–Løken syndrome has been described in children with mutations in the *NPHP3* and *NPHP4* genes.[165,189,190] The majority of children with NPH types 3 and 4 do not have Senior–Løken syndrome; there is no explanation for this variable expression.

Table 22.8 Extrarenal manifestations of nephronophthisis

Tapetoretinal degeneration
Liver fibrosis
Skeletal abnormalities
Mental retardation
Cerebellar ataxia

Some children with NPH have other extrarenal manifestations, including mental retardation,[169,178,191] hepatic fibrosis,[169,191–194] Dandy–Walker syndrome,[178] cerebellar ataxia,[193,195] coloboma,[169] and skeletal anomalies.[169,193,195–197] However, there is some question about the rigor of the renal diagnosis in some of these cases.[198]

Mutations in the *NPHP1* gene have been associated with extrarenal manifestations, including Joubert's syndrome,[199] Cogan's oculomotor apraxia,[200] and the combination of cerebellar ataxia and nystagmus.[201] Mutations in the *NPHP3* gene can cause hepatic fibrosis or tapetoretinal degeneration.[190] Mutations in the *NPHP4* gene can cause Cogan's oculomotor apraxia or tapetoretinal degeneration.[165,202]

The more common possible extrarenal manifestations of NPH are shown in Table 22.8. Many patients with extrarenal manifestations also have tapetoretinal degeneration, and thus are part of the Senior–Løken syndrome.

Radiologic features

By ultrasound, the kidneys are hyperechoic with loss of corticomedullary differentiation; they are of normal or slightly decreased size.[203–205] Medullary cysts are a hallmark of the disease, but they are not always detected by ultrasound.[173,203,204] CT is a more sensitive method for identifying medullary cysts[206] and thin-section CT is recommended.[173]

Diagnosis

The diagnosis of NPH can be challenging, especially in patients without extrarenal manifestations. A history of polyuria and polydipsia, salt craving, disproportionate anemia, a benign urinalysis, and the age of presentation are important clues. The detection of medullary cysts in the setting of chronic renal failure in a child and smallish, echogenic kidneys is virtually

diagnostic. The presence of consanguinity or an affected sibling suggests an autosomal recessive disease and thus strongly supports the diagnosis. Renal histology is potentially helpful in uncertain cases. Genetic diagnosis is now possible because screening for the large chromosomal deletion in the *NPHP1* gene is relatively easy,[207] and this will identify approximately 60% of patients with NPH.[208] Moreover, sequencing of the entire *NPHP1* gene for mutations is commercially available for the small percentage of patients with NPH type 1 who do not have the large deletions. Genetic testing for the other forms of NPH is only available on a research basis. All patients should have an ocular examination to screen for Senior–Løken syndrome and a liver ultrasound to screen for hepatic fibrosis.

Treatment

There is no specific therapy for NPH. Families should be counseled regarding the risk of dehydration due to polyuria. The anemia responds to erythropoietin therapy. Children receive standard therapy for chronic renal insufficiency and ultimately require dialysis and transplantation. The disease does not recur in the kidney transplant and thus transplant is usually quite successful.[186,209] Appropriate specialist care is necessary in children with extrarenal manifestations.

Multicystic dysplastic kidney

Multicystic dysplastic kidney (MCDK) is the most common cystic disease diagnosed during childhood. Most cases are unilateral and asymptomatic; rare bilateral disease is usually fatal at birth as a result of Potter's syndrome.[210] The widespread use of prenatal ultrasound has led to more frequent diagnosis of MCDK, and the approach to the management of these patients is evolving.

The incidence of MCDK is estimated at 1 in 2500 newborns;[211] it is one of the most common fetal anomalies detected by prenatal ultrasound. It occurs slightly more commonly in the left kidney,[212] and the affected child is more likely to be male.[213,214] Given the low incidence of unilateral renal agenesis in neonates, and the much higher incidence of single kidneys in adults, the majority of adults with a single kidney had an MCDK that involuted over time.

MCDK is typically composed of cysts of varying size that do not appear to communicate, and a small amount of abnormal-appearing renal parenchyma. The ureter from the affected kidney is atretic. On microscopic examination, the tissue between the cysts is dysplastic, with undifferentiated mesenchymal cells, often with cartilage, and immature glomeruli and tubules. Occasionally, a few normal-appearing nephrons may be present, explaining the minimal renal function that is infrequently demonstrated on nuclear scan.

Most cases of MCDK are sporadic,[215] although families with putative autosomal dominant inheritance have been described.[215,216] The incidence of MCDK is increased in a variety of syndromes.[217] The pathogenesis of MCDK has been attributed to either early ureteral obstruction[218] or disruption of the normal mechanism of induction of the metanephric blastema by the ureteric bud.[219]

Currently, most cases of MCDK are diagnosed by prenatal ultrasound, with palpable abdominal mass, typically in the neonate, as the second most common presentation.[220–222] Rare cases of diagnosis result from symptoms such as emesis or respiratory compromise as a result of compressive effects.[223] In older children, MCDK is uncommonly diagnosed during the evaluation for abdominal pain or mass, hematuria, or hypertension. In all ages, MCDK may be discovered during the evaluation for UTI or as an incidental finding during abdominal imaging.[224,225]

The diagnosis of MCDK is typically made by ultrasound. In infants with a prenatal diagnosis, a postnatal ultrasound should be performed to confirm the presence of MCDK. The major diagnostic dilemma is differentiation from hydronephrosis.[226] In MCDK, there is typically no communication between cysts, and the larger cysts are not medial. In hydronephrosis, the calices extend outward from the dilated renal pelvis, and there is renal parenchyma surrounding the central cystic structure. The normal reniform shape is usually present with hydronephrosis, but usually absent in MCDK.[227] If the diagnosis is unclear, a radionuclide scan shows uptake of tracer if hydronephrosis is present, but usually no uptake with MCDK. Occasionally, MCDK demonstrates a small amount of uptake,[228,229] and other studies may then be useful in confirming the diagnosis.[226]

Children with MCDK are more likely to have abnormalities of the contralateral kidney.[213,230,231] VUR has been reported in from 4% to 31% of contralateral kidneys.[212,213,230–232] Other reported anomalies include ureteropelvic junction (UPJ) obstruction, ureteral ectopia, uterovesical junction obstruction, ureteroceles, and renal dysplasia.[213,230,231]

The natural history of MCDK is usually gradual involution. In one study, 18% were undetectable by ultrasound at 1 year of age, and 58% were undetectable by 6 years of age.[220] Some MCDK do increase in size during the first few years of life, and complete involution may take more than 20 years.

Hypertension, which is postulated to be renin mediated,[233] has been reported as a potential complication of MCDK.[212,234] There are reports of hypertension being cured following surgical removal of the MCDK.[233] Yet, others have questioned the validity of these reports. For example, in a series of 260 cases, there were only 4 patients with hypertension, which was described as minimal and probably unrelated to the MCDK.[235]

Malignancy is another possible complication of MCDK. There are cases of Wilms' tumor in younger children[236] and renal cell carcinoma in older teenagers and adults,[237] but some question the validity of these reports.[238] The true increase in risk is unclear. Less than 0.1% of the 7500 children enrolled in the National Wilms' Tumor Study Group had an MCDK.[238] A recent systematic review concluded that the risk of malignancy is extremely low.[239]

The management of MCDK is controversial.[234,240,241] There has been a shift from routine surgical removal to non-operative management, consisting of surveillance ultrasounds to screen for Wilms' tumor.[235] There is not a consensus on the frequency of these ultrasound evaluations, especially given the low risk of Wilms' tumor. Ultrasounds are usually done more frequently during the first year of life (e.g. every 3 months), and then less frequently (e.g. every 6–12 months) until approximately age 5 years.[220] Surgical removal (discussed in Chapter 29) is indicated if there is any change that is suspicious for a Wilms' tumor. Other indications for nephrectomy include mass effect, pain, hypertension, and parental preference.

Follow-up, and surgical repair when indicated,[213] of the contralateral kidney is also critical. The follow-up ultrasounds of the MCDK should evaluate the size and echogenicity of the contralateral kidney; there should be compensatory hypertrophy.[212,231] Given the high rate of VUR, a routine voiding cystourethrogram is frequently recommended,[242] although this has been questioned in the child with a normal-appearing contralateral kidney.[213,243]

Medullary cystic kidney disease

Medullary cystic kidney disease (MCKD) is frequently grouped with NPH as the juvenile nephronophthisis/medullary cystic disease complex.[244] However, MCKD is clearly a distinct entity, based on its autosomal dominant inheritance and later onset.[245] Renal failure typically develops during adulthood, although renal insufficiency may be apparent in some children.[202,245,246] In some families, the disease is not apparent until a mean age of over 60 years.[247] Hyperuricemia and gouty arthritis, occasionally diagnosed in childhood,[246] may be the presenting manifestation.[248,249] Other clinical features include polyuria, anemia, and hypertension.[250,251] The kidneys are usually of normal size or small, and renal imaging may show a few medullary cysts, but the absence of visible cysts is relatively common.[246] The urinalysis is typically benign, except for low-grade proteinuria in a minority of patients.[250] Histologic examination demonstrates interstitial nephritis; thickening and splitting of the basement membrane is the most notable feature.[246,252]

Mutations in *UMOD*, the gene encoding uromodulin (also called Tamm–Horsfall protein), cause MCKD type 2.[253] Mutations in *UMOD* also cause the autosomal dominant disorder, familial juvenile hyperuricemic nephropathy (FJHN).[253,254] It is now clear that MCKD type 2 and FJHN are the same disease, since they are genetically allelic and clinically indistinguishable.[246,253,255] The dominant features are chronic renal failure and gout.[252] Genetic diagnosis, by sequencing of exons 3 and 4, the site of most mutations in this disorder, is commercially available. The locus for MCKD type 1 has been identified on chromosome 1.[247] These patients tend to have fewer manifestations of hyperuricemia than patients with MCKD type 2 and a later onset of renal insufficiency.[250] There is evidence for additional genetic heterogeneity.[250,256]

Medullary sponge kidney

Medullary sponge kidney (MSK) is predominantly a disease of adults, but occasionally presents in childhood.[257–259] The intrapapillary collecting ducts are dilated and multiple small cysts may be present. Not all renal pyramids are always affected, providing an explanation for the often asymmetric and focal appearance. This does not appear to be an inherited disease, although a few family clusters are described.[260,261]

The diagnosis of MSK is based on the characteristic changes on IVP, which shows stagnation of contrast in one or more renal papillae due to dilation of

Figure 22.10 IVP demonstrating bilateral medullary sponge kidneys in a 9-year-old girl who presented with hematuria. Note the characteristic radial stretching and puddling that represent the contrast-filled dilated collecting tubules in this disease. (From Glassberg et al.[262])

the collecting ducts (Figure 22.10). The resultant image has been described as a 'pyramidal blush'.[263] These changes are sometimes misdiagnosed as papillary necrosis.[260] A CT scan is not as sensitive for making the diagnosis of MSK, but it has a superior ability to detect the papillary calcifications that frequently complicate MSK.[258,264,265] Ultrasound also frequently detects this nephrocalcinosis, which may not be visible on a plain film.[258]

Clinically, patients are at increased risk for hematuria, UTI, and nephrolithiasis. There may be impairment of urinary concentrating ability[258] or urinary acidification (renal tubular acidosis [RTA]), but the GFR is normal.[266,267] The urinary concentrating defect can lead to complaints of polyuria in a child.[258] The increased risk of nephrolithiasis and nephrocalcinosis[268–270] is probably secondary to stagnation in the dilated collecting tubules and an increased incidence of hypercalciuria,[271] hypocitraturia, and hypomagnesuria.[272,273] Patients with RTA are more likely to have hypercalciuria or hypocitraturia, and the acidification defect may be the primary problem.[271,272,274] Nevertheless, even patients without a defect in urinary ion excretion have an increased risk of nephrolithiasis,[270] arguing for a role of the dilated tubules.[275]

The RTA in MSK, when present in a child, can lead to growth retardation.[259] RTA is sometimes associated with severe potassium wasting and this can lead to symptomatic hypokalemia.[276]

Hematuria is usually mild, but massive bleeding is occasionally seen.[277] More commonly, MSK is the explanation for asymptomatic microscopic or gross hematuria, and these are frequent complaints in pediatric cases.[257,258]

The increased risk of UTI may be related to stasis in the dilated tubules and the presence of stones, which may cause obstruction or act as a nidus of infection. UTI in MSK is occasionally complicated by abscess formation.[278]

Associated anomalies reported with MSK include hemihypertrophy,[259,279–283] Caroli's disease,[284,285] hyperparathyroidism[286,287] and a variety of miscellaneous disorders.[261,288,289]

Most patients require limited treatment. Nephrolithiasis is successfully treated by the usual approaches, including extracorporeal shock wave lithotripsy (ESWL).[290] Patients with MSK and RTA have a good response to alkali therapy, with decreased hypercalciuria and stone formation.[271,291] UTIs are treated conventionally, with the caveat that an abscess should be suspected if the patient does not respond.[278]

Glomerulocystic kidney disease

Glomerular cysts are present in a variety of diseases (Table 22.9); the diagnosis is made by kidney biopsy. The term 'glomerulocystic kidney disease' is reserved for patients who do not have an underlying disease such as ADPKD. As detailed below, glomerulocystic kidney disease (GCKD) is not a uniform, well-defined entity; rather it describes a heterogeneous group of patients who have been grouped into categories based on apparent inheritance and kidney size.

Glomerular cysts may be seen in children with a variety of severe, usually inherited, malformation syndromes (see Table 22.9).[292–299] Many of these

Table 22.9 Diseases with glomerular cysts

Syndromes with glomerular cysts:
■ Brachymesomelia–renal syndrome
■ Oral–facial–digital syndrome
■ Glutaric acidemia type II
■ Trisomy 18
■ Renal retinal dysplasia
■ Short-rib polydactyly syndrome type II
■ Tuberous sclerosis
■ Zellweger syndrome
■ Autosomal dominant polycystic kidney disease
■ Sporadic glomerulocystic kidney disease
■ Familial hypoplastic glomerulocystic kidney disease
■ Autosomal dominant glomerulocystic kidney disease

patients have accompanying renal dysplasia. Again, these patients have glomerular cysts, but do not have GCKD.

Glomerular cysts are seen in ADPKD, but most patients also have cysts involving other segments of the nephron.[123,300,301] However, there are cases of GCKD in children with a strong family history of ADPKD.[90,302] This suggests that, in these patients, GCKD is a variant of ADPKD, with predominance of glomerular cysts. In fact, one child had GCKD on initial biopsy, but subsequently had pathologic findings consistent with ADPKD.[302] It has also been hypothesized that some patients with 'sporadic' GCKD may, in fact, have ADPKD, either due to a new mutation or because of incomplete family studies.

Children with sporadic GCKD have a variable presentation. The kidneys are frequently enlarged at birth, with a loss of corticomedullary differentiation.[303,304] Kidney size may normalize,[304] and occasionally the medulla is of normal echogenicity despite an echogenic cortex.[303] Ultrasound and MRI can identify cortical cysts.[41,305] Renal function may be normal[303,304] or decreased.[306,307] Other cases of sporadic GCKD present in adults; these patients may have mild[57,308] or severe[309–311] renal failure, typically with enlarged kidneys.

There is an autosomal dominant form of GCKD that is associated with small (hypoplastic) kidneys and malformed or absent calices.[312,313] These children have a decreased GFR at birth, but then renal function remains fairly stable. Some of these patients have been growth retarded,[313] and a few have a noticeable prognathism.[312,313] In some families, hypoplastic GCKD is secondary to mutations in hepatocyte nuclear factor (HNF)-1β.[314–316] Heterozygous mutations in HNF-1β may also cause maturity-onset diabetes of the young (MODY), and thus affected patients may have renal disease and diabetes.[314–316]

The remaining families with GCKD have normal or increased kidney size. In one family with apparent autosomal dominant inheritance, kidney size and kidney function were normal, but those affected had an abnormal ultrasound.[317] In another family, a 10-year-old girl with an affected father had a mildly depressed GFR.[318] Melnick et al[319] describe three siblings and their father; all had normal kidney size but a decreased GFR. Finally, a large family with GCKD was extensively studied by Sharp and colleagues.[320] These patients had hypertension, and renal function ranged from normal to ESRD. The kidneys were large and echogenic; pelvocaliectasis and a hypoechoic cortical rim were additional sonographic features. Inheritance was autosomal dominant and linkage analysis indicated that neither the *PKD1* gene nor the *PKD2* gene was responsible for this family's disease.[320]

Simple renal cysts

The increased use of radiologic testing has led to the identification of more children with simple cysts, which may be solitary or multiple. The incidence of simple cysts increases with age.[321–324] Fewer than 0.3% of children have simple renal cysts, and they are usually not associated with subsequent problems.[325] Cysts in children usually do not increase in size, and single cysts are commonly located in the right upper pole.[325] However, the presence of even a single cyst in the context of an appropriate family history supports a diagnosis of ADPKD.[134] The incidence of simple renal cysts is increased in children with acquired immunodeficiency syndrome (AIDS).[326] Simple renal cysts are rarely detected by fetal ultrasonography, and the majority resolve before delivery.[327]

Simple renal cysts do not impair renal function,[325,328] except in rare instances.[329] They may play a role in causing infection[330] or hypertension[322,329,331,332] in some patients. Cysts in children occasionally cause pain.[333,334] Symptomatic cysts can be treated by percutaneous drainage, although they usually recur unless a sclerosing agent is injected. Injection of the cyst with either alcohol[335,336] or tetracycline[333] prevents recurrence. Surgical marsupialization is rarely necessary. Because cysts frequently occur in the upper pole, it is sometimes difficult to differentiate a cyst from upper pole hydronephrosis due to an obstructed ureterocele or an ectopic ureter. Such a diagnostic dilemma can be resolved by cyst aspiration.[333,337] Cyst fluid has the same blood urea nitrogen (BUN) and creatinine concentration as the patient.[337] Most children with simple renal cysts only need routine ultrasound follow-up, unless the cysts are atypical and therefore suggestive of a malignancy.

Multilocular cysts

A multilocular cyst is a unilateral, benign tumor of the kidney. Approximately half the cases occur in children, with the remainder in middle-aged adults.[338] The children are more likely to be male, whereas the adults are more likely to be female. Children are usually <2 years of age, and the most common presenting complaint is an abdominal mass.[338,339]

Pathologically, the multilocular cyst is well encapsulated and non-infiltrating. The multiple cysts, which do not communicate, are typically separated by fibrous tissue, although embryonic tissue is sometimes present, especially in pediatric cases. The cysts are well visualized by a CT scan or ultrasound. The differential diagnosis includes Wilms' tumor, ADPKD, or a multicystic dysplastic kidney. Occasionally, a second multilocular cyst appears months later in the contralateral kidney.[340]

Because of the possibility of a cystic Wilms' tumor, surgical resection is recommended.[338] Nephrectomy is sometimes the only option, but increasing numbers of cases are managed with renal preserving surgery.[338,340]

Acquired cystic kidney disease

Kidney failure is sometimes associated with cyst formation in a previously non-cystic kidney. Acquired cystic kidney disease (ACKD) occurs in patients with renal failure, including dialysis patients, transplant patients, and chronic renal failure patients. ACKD occurs in children and the number of cysts increases over time.[341–345] Children with ACKD are at a low risk for gross hematuria and retroperitoneal hemorrhage.[342] More ominously, a small percentage of children develop renal cell carcinoma.[343,345] Because of this possibility, periodic ultrasound screening of dialysis patients is necessary and children with suspicious lesions should have a nephrectomy.

Syndromes with cystic kidneys

A large number of syndromes are associated with cystic kidneys. These are mostly rare diseases and many are neonatally fatal. We will briefly review the major features of a few prominent entities, emphasizing those with a defined genetic etiology.

Tuberous sclerosis

Although classified as one of the neurocutaneous syndromes, renal involvement is an important cause of morbidity and mortality in tuberous sclerosis (TS).[346,347] Patients with TS develop hamartomas in a variety of organs, including angiomyolipomas of the kidneys. The major extrarenal manifestations of TS are summarized in Table 22.10. Most of the features of TS become more prominent over time, except for cardiac rhabdomyomas, which tend to regress during childhood.[348] The hypopigmented macules (ash-leaf spots) are especially helpful diagnostically, since they are often visible at birth and are eventually present in over 97% of children;[349] use of a woods lamp, especially in light-skinned individuals, may aid in their identification. Facial angiofibromas, which may be confused with acne, and shagreen patches are also extremely common. Neurologic lesions include multiple calcified tubers, disorders of neuron migration, and giant cell astrocytomas. The neurologic manifestations, with both seizures and developmental delay, are often the dominant clinical feature. Tumors of the kidney are the most common cause of malignancy in TS, but a variety of extrarenal cancers are also seen in adults and children.[350,351]

Table 22.10 Extrarenal manifestations of tuberous sclerosis

Neurologic:
- Cortical tubers
- Seizures
- Mental retardation
- Intracranial aneurysms
- Retinal hamartoma

Cutaneous:
- Hypopigmented macules
- Facial angiofibromas
- Shagreen patch
- Café-au-lait macules
- Molluscum fibrosum pendulum
- Forehead fibrous plaque
- Periungual fibromas
- Confetti-like macules

Cardiac:
- Rhabdomyomas
- Wolff–Parkinson–White syndrome

Bone:
- Sclerosis
- Cystic changes

Pulmonary lymphangiomyomatosis

TS is an autosomal dominant condition, but two-thirds of the cases are due to new mutations, so most patients will not have a positive family history. There is variable penetrance and thus affected parents usually have mild disease and may be undiagnosed. TS is caused by mutations in either the *TSC1* gene on chromosome 9[352] or the *TSC2* gene on chromosome 16.[353] Both of these genes encode tumor suppressors and the hamartomas arise because of mutations in the normal wild-type gene.[354,355] Intellectual disability is more common in patients with mutations in the

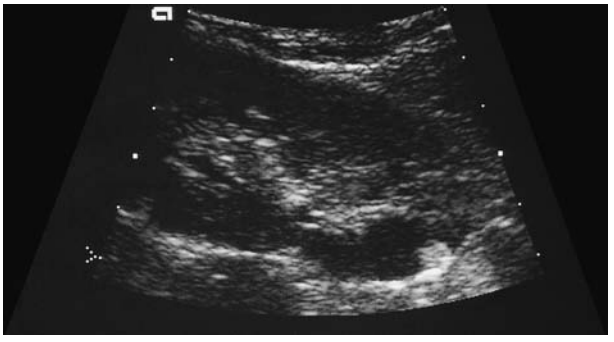

Figure 22.11 Ultrasound of a child with angiomyolipomas due to tuberous sclerosis. This case shows the hyperechoic fat (without shadowing) of an angiomyolipoma. (Courtesy of Dr J Sty, Children's Hospital of Wisconsin.)

Figure 22.12 Renal CT of a child with cysts due to tuberous sclerosis. Multiple cysts are visible. (Courtesy of Dr J Sty, Children's Hospital of Wisconsin.)

TSC2 gene.[356,357] The *TSC2* gene is located adjacent to the *PKD1* gene on chromosome 16.[72] Some children have large chromosomal deletions that affect both the *TSC2* gene and the *PKD1* gene and these children tend to have severe polycystic kidney disease.[72,358] This contiguous gene syndrome is present in the majority of children with early, severe polycystic kidney disease and TS.[359]

Angiomyolipomas are the most common renal lesion in TS and are readily seen by CT or ultrasound (Figure 22.11). Angiomyolipomas are usually not detected in the first few years of life but they are ultimately found in most children with TS and they tend to increase in size during childhood.[360,361] Larger angiomyolipomas are sometimes associated with pain.[347] Hematuria is uncommon.[362] However, retroperitoneal bleeding from angiomyolipomas can be life threatening[346] and presents with sudden flank pain, a palpable abdominal mass, and symptoms of anemia. Clinical manifestations of angiomyolipomas are relatively uncommon in children.[363,364]

Renal cysts (Figure 22.12) are less common than angiomyolipomas and sometimes disappear on subsequent evaluation.[360] Renal malignancies, including renal cell carcinoma and malignant angiomyolipomas, are a serious concern in TS and both are seen in children, sometimes in early childhood.[350,360]

Both renal cysts and angiomyolipomas cause destruction of normal renal tissue, and this can lead to renal failure in adults[365] and children.[359] The risk of renal failure and hypertension is greater in patients with cystic disease.[366–368] Children with disruption of the contiguous *PKD1* and *TSC2* genes usually have severe cystic disease and are at high risk for hypertension and early kidney failure.[359]

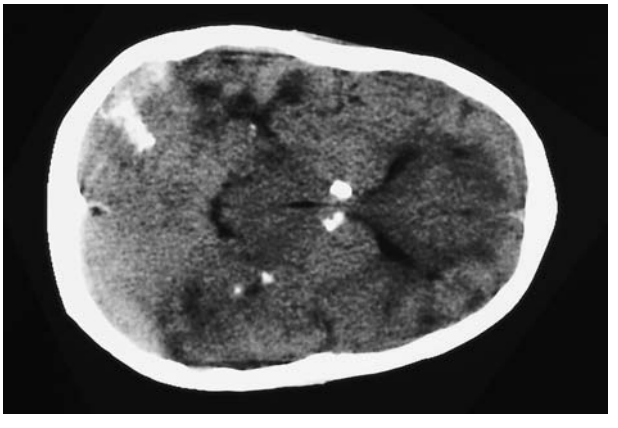

Figure 22.13 Head CT of the same child shown in Figure 22.12. Subendymal calcific densities are present in the region of the foramen magnum. (Courtesy of Dr J Sty, Children's Hospital of Wisconsin.)

The diagnosis of TS is based on the classic clinical features, although genetic testing is commercially available. The possibility of TS should be suspected in a young child with large renal cysts suggestive of early-onset ADPKD. These children may have the contiguous gene syndrome with a deletion affecting both the *PKD1* and *TSC2* genes. A family history of TS is often not present due to variable penetrance and a high rate of new mutations. A search for skin manifestations is usually helpful, although cutaneous manifestations are less prominent or sometimes absent in infants.[349] Young children have fewer cortical tubers than older patients but MRI is quite sensitive for detecting other subtle findings in infancy.[369] Although MRI is more sensitive, most children have the mineralized subendymal nodules that are visible by CT (Figure 22.13).

Children with TS require the input of multiple specialists. All children with TS should have a renal ultrasound at diagnosis and follow-up renal ultrasounds every 1–3 years, with frequency dictated by the specific clinical situation.[370] Patients with extensive or rapidly changing lesions require more frequent follow-up. Those with more severe kidney disease may require CT or MRI to screen for malignant changes. Differentiating angiomyolipomas from malignancy requires careful comparison of sequential images. Patients with kidney failure are treated with dialysis[365] and transplantation.[371] Because of the risk for renal hemorrhage and malignancy, there is an argument for bilateral nephrectomies in children who progress to ESRD, especially those with large angiomyolipomas.

Meckel's syndrome

Meckel's syndrome, sometimes called Meckel–Gruber syndrome, is a lethal autosomal recessive disorder. The most common extrarenal manifestations are posterior encephalocele, polydactyly, and hepatic fibrosis and cysts; however, a variety of other findings may also be present.[372,373] Cystic dysplasia of the kidneys is present in all cases.[372,373] Multiple genetic loci for Meckel's syndrome have been identified.[374–376]

Von Hippel–Lindau disease

Von Hippel–Lindau (VHL) disease is a rare autosomal dominant disorder with variable penetrance. The most prevalent manifestations are cerebellar hemangioblastoma, retinal angioma, pancreatic cysts, renal cell carcinoma, spinal hemangioblastoma, and pheochromocytoma.[377,378] Renal cysts are also common but, like renal cell carcinoma, they are rarely seen in childhood.[377,378] A mutation in a tumor-suppressor gene, located on chromosome 3, causes VHL disease;[379] genetic testing is commercially available.

Acute renal failure

23

Lawrence Copelovitch, Bernard S Kaplan, and Kevin EC Meyers

Introduction

Acute renal failure (ARF) is defined as a sudden decrease of normal kidney function that compromises the normal renal regulation of fluid, electrolyte, and acid–base homeostasis.[1] In practical terms ARF is characterized by a reduction in the glomerular filtration rate (GFR), which results in an abrupt increase in the concentrations of serum creatinine and blood urea nitrogen (BUN). The effect on urine volume in ARF is variable: patients may be anuric, oliguric, and, in some cases, polyuric. ARF develops over a period of hours to days, whereas chronic renal failure (CRF) progresses over months to years. In many circumstances there is little difficulty in discerning between ARF and CRF. Short stature, renal osteodystrophy, delayed puberty, normocytic anemia, and hyperparathyroidism all suggest CRF. However, it may be difficult to differentiate ARF from CRF without imaging studies and a kidney biopsy. Furthermore, at the time of presentation, a patient with CRF may have a superimposed ARF – this is referred to as acute on chronic renal failure. ARF is usually encountered in pediatric urologic patients as a complication of underlying chronic renal disease. The three most important contexts in pediatric urologic practice are acute pyelonephritis, aminoglycoside toxicity, and acute obstructive uropathy. Urologists must be alert to the possibility of ARF in any patient referred with macroscopic hematuria. The three most important contexts are urinary tract infection, glomerulonephritis, and myoglobinuria. Extracorporeal shock wave lithotripsy (ESWL) is the urologic treatment of choice for the majority of patients with renal or proximal ureteral stones.[2] Very rarely, bilateral or unilateral ESWL has been associated with ARF even in the absence of obstruction.[3] In order to diagnose the underlying cause of ARF and treat the metabolic complications, all patients should undergo a full evaluation by a pediatric nephrologist at the time of presentation.

Table 23.1 Causes of non-oliguric acute renal failure

Furosemide may convert oliguric renal failure to non-oliguric renal failure
Nephrotoxins
Non-fulminant acute viral hepatitis
Primary lymphoma of the kidney
Severe exertional rhabdomyolysis
Hemolytic uremic syndrome (HUS)

The likelihood of recovery from, and appropriate treatment of ARF, depends on the amount of urine output and the underlying cause. Quantifying the urine output is essential, because the amount of urine will often predict the clinical course and may aid in identifying the underlying renal insult. Patients with non-oliguric or high-output ARF (Table 23.1) have lower complication rates and higher survival rates than those with anuric or oliguric ARF.[4] Furthermore, children with acute interstitial nephritis or nephrotoxic renal insults, including aminoglycoside nephrotoxicity, are more likely to have ARF associated with either normal or increased urine output. In contrast, children with renal hypoperfusion injury, acute glomerulonephritis, hemolytic uremic syndrome (HUS), or other causes are more likely to have ARF associated with anuria or oliguria. The underlying cause of ARF may be classified as prerenal failure, intrinsic renal disease, or postrenal failure. It is important to note that many cases of ARF are multifactorial, especially in hospitalized children.

Prerenal failure

In prerenal ARF, renal function may be initially normal, but severe and/or prolonged renal hypoperfusion leads to renal injury and intrinsic ARF. Prerenal ARF results from renal hypoperfusion caused by intravascular volume contraction, decreased effective

circulating blood volume, or from altered intrarenal hemodynamics. True intravascular volume contraction results from dehydration, acute blood loss, or extravascular accumulation of fluid – so-called third spacing of fluid. This is most often encountered in patients with the systemic inflammatory response syndrome or with hypoalbuminemia. Infants are particularly vulnerable to excessive volume loss. They have a proportionally higher percentage of insensible water losses and, in addition, cannot maximally concentrate their urine as a result of immature kidneys. Decreased effective blood circulation occurs when the true blood volume is normal or increased but renal perfusion is decreased. This occurs in left-sided heart failure, cardiac tamponade, or hepatorenal syndrome.[5] Intrarenal afferent arteriolar vasoconstriction occurs in hepatorenal syndrome, calcineurin toxicity, and non-steroidal anti-inflammatory drug (NSAID) use; intrarenal efferent arteriolar vasodilation occurs with the use of angiotensin-converting enzyme (ACE) inhibitors. Afferent arteriolar vasoconstriction or efferent arteriolar vasodilation decreases the glomerular filtration.

In prerenal ARF, the kidneys are intrinsically normal and the reduced GFR and urine output are appropriate physiologic responses to the reduced renal blood flow. In the early stages, restoration of renal perfusion results in a prompt return of renal function to normal. If the insult is prolonged, acute tubular necrosis (ATN) may develop and the ARF will not immediately correct with improved renal perfusion. This signifies the progression to intrinsic renal disease. The evolution from prerenal failure to intrinsic renal disease is a gradual process because there are a number of compensatory mechanisms that maintain adequate renal perfusion. The two primary mediators of the intrarenal compensatory mechanism are the prostaglandins (PGI_2, PGE_2, and PGD_2) and angiotensin II. The prostaglandins promote compensatory vasodilation of the glomerular afferent arterioles in an attempt to maintain adequate blood flow and preclude further deterioration of renal function.[6] Angiotensin II causes a preferential constriction of the glomerular efferent arterioles, which increases glomerular filtration pressure.[7] The dilation of the afferent arteriole and constriction of the efferent arteriole work in concert to promote an increased filtration fraction and thereby maintain the GFR. Furthermore, angiotensin II, through direct action on the proximal tubule and through the effect of aldosterone on the distal tubule, causes increased sodium and water reabsorption. This helps to maintain an appropriate intravascular volume at the expense of a decreased urine output.

Intrinsic renal disease

When ARF is the result of intrinsic renal pathology, attempts are made to define the location of the insult. Renal injury may occur at the level of the renal vasculature, tubules, interstitium, or glomeruli. The basic mechanisms of renal injury include hypoperfusion, ischemic cell damage, toxin-mediated cell injury, and inflammation. The inevitable outcome is varying degrees of cellular death as a result of necrosis or apoptosis.[8]

Vascular injury

Vascular injury may occur in large vessels, such as in renal artery thrombosis and renal vein thrombosis (RVT), or in the microvasculature, as in HUS and thrombotic thrombocytopenic purpura (TTP). Both renal artery thrombosis and RVT occur most commonly in newborn infants, whereas HUS is most common in young children. Conversely, TTP is rarely seen in pediatrics. Renal artery thrombosis is often associated with umbilical artery catheters and may result in hypertension. ARF rarely occurs unless there is a solitary kidney or the thrombosis is bilateral. In newborns, RVT is associated with maternal diabetes, polycythemia, and sepsis. Coagulation defects are increasingly being identified in neonates with RVT. In childhood, RVT is more closely associated with severe dehydration, nephrotic syndrome, and congenital hypercoagulable states.[9] RVT may present with large palpable kidneys, gross hematuria, hypertension, or oliguria. The neonate with RVT is usually very ill but the condition may also be clinically silent.

The classic triad seen in HUS is acute hemolytic anemia with fragmented erythrocytes, thrombocytopenia, and ARF. The illness is usually preceded by an episode of acute gastroenteritis, often accompanied by bloody diarrhea. Sudden onset of pallor usually develops several days after the diarrheal illness resolves. Oliguria is a common feature and one clue to making an early diagnosis is that the urine output remains decreased even with appropriate rehydration. The condition is usually caused by *Escherichia coli* O157:H7, a Shiga toxin-producing strain. The Shiga toxin is directly toxic to the glomerular vascular endothelium, where it initiates local coagulation (thrombotic microangiopathy), and to renal tubules,

where it induces ATN. Several other strains of *E. coli*, as well as *Shigella dysenteriae* and *Aeromonas* produce similar toxins that cause HUS. Non-diarrhea-associated HUS is a much less common condition that is caused by *Streptococcus pneumoniae* infections. Additional causes include bone marrow transplantation, human immunodeficiency virus (HIV) infection, and medications. Inherited causes include deficiencies of factor H, factor I, and membrane cofactor protein (CD46).

Glomerular injury

Acute glomerulonephritis (AGN) is common in school-age children but rare in children under the age of 2 years. Postinfectious glomerulonephritis is the most common cause in childhood. Anti-GBM (glomerular basement membrane) antibody disease, ANCA (antineutrophil cytoplasmic autoantibody) positive (pauci-immune) glomerulonephritis, lupus nephritis, immunoglobulin A (IgA) nephropathy, Henoch–Schönlein purpura nephritis, and membranoproliferative glomerulonephritis all cause ARF.[8] The clinical features of AGN include hypertension, oliguria, painless cola-colored gross hematuria, and edema that is more often periorbital than pedal; laboratory findings include proteinuria, red blood cell (RBC) casts, an increased serum creatinine concentration, evidence of antecedent streptococcal infection, and a low serum complement C3 concentration. Glomerular hypercellularity and inflammation result in a decreased GFR, reduced urine output, retention of potassium, and signs of fluid overload. The tubules and interstitium are mostly spared during the inflammatory process. Each of the glomerulonephritides can lead to rapidly progressive glomerulonephritis (RPGN). This condition is characterized by oligoanuria, rapidly rising serum creatinine, and extensive crescent formation on renal biopsy. A diagnosis of RPGN must be made as soon as possible because treatment with corticosteroids, often used together with plasmapheresis, is essential in order to preserve renal function.

Tubular injury

Tubular injury is also known as acute tubular necrosis (ATN) and is the end result of either ischemic or toxin-mediated damage to the tubules. The tubular epithelial cells are particularly sensitive to anoxia and are vulnerable to toxins. The cells of the straight segment of the proximal tubule and the thick ascending limb of the loop of Henle are highly dependent on oxidative phosphorylation. This serves to maintain their high energy demand, which is required for their transport functions. As a result, they are particularly susceptible to ischemia and to nephrotoxins that disrupt energy supply or mitochondrial function.[10]

Ischemia-induced ATN is the result of renal hypoperfusion. If the insult is prolonged and severe, prerenal ARF may progress to ATN that is no longer immediately reversible with restoration of appropriate renal perfusion. Tubular epithelium damage results in the release of vasoactive compounds that increase afferent arteriolar resistance, thereby decreasing renal blood flow and perpetuating tubular injury. This process is known as tubuloglomerular feedback and plays an important role in the progression from renal hypoperfusion to tubular injury. The vasoconstriction is exacerbated by adrenergic stimulation, decreased intrarenal prostaglandin synthesis, and increased angiotensin II formation.[8] The decrease in GFR is further reduced by the intraluminal tubular obstruction caused by the debris formed from sloughing tubular cells as they undergo apoptosis. The denuded tubular epithelium allows tubular back-leak of glomerular filtrate into the medullary interstitium where it is returned to the systemic circulation. Tubuloglomerular feedback, intraluminal tubular obstruction, and tubular back-leak are all interrelated in the complex pathogenesis of ARF.[11] Several other vasoactive compounds, including endothelin and nitric oxide, are implicated in the progression of ARF but their roles are not fully elucidated.

The clinical course of ischemia-induced ATN comprises the anticipation phase, the initiating phase, the maintenance phase, and the recovery phase.[12] During the initiating phase, the only signs might be a slight decrease in urine output and a rise in serum creatinine concentration and BUN. The maintenance phase is characterized by oliguria, fluid overload, acidosis, hyperkalemia, and a more rapid decline in GFR (usually with oliguria or anuria). Polyuria in the context of increasing serum creatinine concentrations is known as non-oliguric ARF. The recovery phase is characterized by polyuria, kaliuresis, and hypokalemia, while the serum creatinine and BUN begin to return to normal. The recovery process may take weeks to months, and more subtle impairments of tubular function may persist for even longer. If the ATN is prolonged and severe, the child may develop cortical necrosis, which is often associated with only partial recovery of renal function.

Many medications, poisons, or endogenous toxins can cause toxin-mediated ATN. Common nephrotoxic medications are aminoglycosides, amphotericin,

Table 23.2 Nephrotoxins

Aminoglycosides	Amphotericin
Trimethoprim	Sulfinpyrazone
Acyclovir	Fluoroquinolones
Mefenamic acid	Cisplatin
NSAIDs	Acetaminophen
Ifosfamide	Calcineurins
Diethylene glycol	Paraquat

acyclovir, cisplatin, and radiocontrast agents (Table 23.2).[8]

Aminoglycoside nephrotoxicity occurs in 10–26% of patients[13] usually after 1 week of treatment, although the ARF may be delayed until after discontinuation of the medication. The renal injury usually presents with a decrease in urine concentrating capacity, and is usually transient, mild, and non-oliguric. Serum and urine electrolyte abnormalities range from combinations of hypokalemia, hypomagnesemia, and hypocalcemia to a complete acquired Fanconi syndrome or an acquired Bartter syndrome.[13,14] Accumulation of aminoglycosides in the lysosomes of the proximal tubules induces cell necrosis and the excretion of low molecular weight proteins (β_2-microglobulin) and brush border enzymes. Risk factors for aminoglycoside-induced ARF are extremes of age, hypovolemia, pre-existing renal insufficiency, multiple nephrotoxic agents, hypokalemia, hypomagnesemia, prolonged use, total lifetime exposure, and elevated peak and trough levels.[8,11] It is important to note that studies in humans are dogged by confounding variables of the critically ill and that the choice of an aminoglycoside should not be governed by nephrologic criteria; the dosing, however, must be adjusted for the level of GFR. In most cases there is full recovery, with no evidence of permanent injury or CRF.

Patients with amphotericin B-induced renal injury often present with non-oliguric ARF. Amphotericin B injures many different nephron segments as well as the collecting duct. In addition to toxin-mediated ARF, amphotericin B may also cause hypokalemia and hypomagnesemia. Distal renal tubular acidosis occurs as a result of back-leakage of hydrogen ions into the interstitium.[8] Risk factors for the development of ARF include maximal daily dose, duration of therapy, and concomitant use of cyclosporin A.

Acyclovir-induced ARF is usually non-oliguric and may present with microscopic hematuria. Acyclovir is relatively insoluble in urine and, by forming crystals within the renal tubule, causes intratubular obstruction and a reduced GFR. Risk factors for the development of ARF include high doses, rapid intravenous administration, hypovolemia, and pre-existing renal disease.[8]

Radiocontrast-induced nephropathy is uncommon in children and is usually mild and transient. The pathogenesis is unclear. Risk factors for contrast nephropathy include underlying renal disease, dehydration, large doses of contrast media, congestive heart failure, diabetes mellitus, NSAIDs, and ACE inhibitors.[11]

Poison-mediated ATN may occur from direct tubular toxicity, as in mercury poisoning, or from crystal formation, as in ethylene glycol and methanol poisoning. Both ethylene glycol and methanol are non-toxic until they are metabolized by alcohol dehydrogenase into their metabolites. Once their metabolites have been generated, crystals will form in the tubules, causing obstruction and ARF.[8]

Endogenous toxins that can cause ATN are myoglobin, hemoglobin, and uric acid. Pigment-induced ATN can be precipitated by either hemoglobinuria or myoglobinuria. Tubular injury results from the precipitation of pigment in the tubules and heme protein-induced oxidative stress.[11] Myoglobin- or hemoglobin-induced ARF is more likely to develop in the presence of dehydration, metabolic acidosis, severe muscle damage, or multiple organ failure. Rhabdomyolysis is caused by viral infections (influenza), medications (statins), seizures, prolonged exercise, or illicit drug use (Table 23.3). An elevated serum creatine phosphokinase level can confirm the diagnosis. The association between cocaine and rhabdomyolysis has been widely reported, whereas the association with amphetamines has only been described in case reports. Cocaine appears to have direct toxic effects on skeletal muscle as well as vasoconstrictive properties, which lead to muscle ischemia.[15] Several proposed mechanisms have been put forward to explain methamphet-

Table 23.3 Causes of rhabdomyolysis

Cocaine/methamphetamine ingestion

amine-induced rhabdomyolysis, although direct myocyte toxicity has never been demonstrated. Amphetamine users are often agitated and experience uncontrolled choreiform movements. The rhabdomyolysis might occur in a fashion similar to the exertional rhabdomyolysis after exhaustive physical exercise.[15,16] Hemolysis occurs in sickle cell disease, immune-mediated hemolysis, or glucose-6-phosphate dehydrogenase (G6PD) deficiency.[11]

Treatment of pigment-induced ARF includes volume expansion, forced diuresis with a loop diuretic, and alkalinization of the urine to increase pigment solubility.[8] An increasing serum creatinine concentration with fluid overload, despite adequate treatment, is an indication for hemodialysis.

Tumor lysis syndrome can be caused by excessive release of uric acid, phosphorus, and cell products, usually during treatment of acute lymphocytic leukemia or B-cell lymphoma. The probable mechanism of injury is related to precipitation of uric acid crystals in the tubules, with obstruction of urine flow. The highest risk for tumor lysis syndrome is with the most rapidly growing tumors or during induction chemotherapy.

Aggressive hydration, with the administration of allopurinol, helps to decrease the uric acid burden and the risk of tubular precipitation. Rasburicase (urate oxidase) is an effective alternative to allopurinol for rapidly reducing uric acid levels, improving patients' electrolyte status, and reversing renal insufficiency. Screening for G6PD deficiency is essential prior to rasburicase administration, as it may cause hemolytic anemia and methemoglobinemia in susceptible patients.[17] Dialysis may be necessary if the metabolic abnormalities cannot be controlled with the aforementioned medical management.

Interstitial injury

Interstitial nephritis most often occurs as a result of exposure to medications. It is also associated with infections, systemic diseases, tumor infiltrates, or genetic conditions. In many cases no cause is found. Medications commonly associated with interstitial nephritis include extended-spectrum penicillins, NSAIDs, sulfonamides, and rifampin. Almost every known medication has been implicated. The pathogenesis of medication-induced acute interstitial nephritis is thought to be a hypersensitivity-type or allergic reaction that causes an inflammatory reaction mainly in the medullary interstitium. Many patients are asymptomatic or have vague complaints. Typical symptoms include fever, rash, arthralgias, and flank pain. Urine output is usually increased or normal because this the most frequent cause of non-oliguric ARF. It is important to note interstitial nephritis does not present with gross hematuria or isolated microscopic hematuria and the urine may be bland or there may be combinations of microscopic hematuria, mild proteinuria, pyuria, white blood cell (WBC) casts, eosinophiluria, and peripheral eosinophilia. Acute pyelonephritis, Epstein–Barr virus (EBV), and cytomegalovirus (CMV) also cause interstitial nephritis. Sarcoidosis and tubulointerstitial nephritis and uveitis (TINU) are rare causes.

Postrenal failure

Congenital obstructive uropathies are among the most frequent causes of CRF in pediatrics; this is often erroneously referred to as ARF when the presentation is in the newborn child. ARF is rarely the result of postrenal obstruction, except when this occurs in solitary kidneys either from aplasia or transplantation. In pediatric individuals with two functioning kidneys, postrenal ARF will occur only with urethral obstruction, bladder neck obstruction, or bilateral ureteric obstruction, because a single normal kidney has sufficient ability to maintain a normal GFR. Most patients with acute obstruction leading to ARF have oliguric ARF, although non-oliguric ARF can occur with partial obstruction. Renal calculi, ureteral blood clots, retroperitoneal fibrosis, neurogenic bladder, bladder tumors and urethral strictures can cause an obstruction at different levels of the urinary tract and lead to ARF.[11] During acute obstruction a decreased GFR is the result of a rise in the intraluminal tubular pressure. A further decline in renal function is caused by arteriolar vasoconstriction. A prompt diagnosis is necessary to provide appropriate urologic intervention. Hydronephrosis detected by renal ultrasound is an important finding. All patients with suspected obstruction should undergo bladder catheterization, as it may be therapeutic as well as diagnostic. Percutaneous nephrostomy, lithotripsy, ureteral stenting, and urethral stenting are indicated when appropriate.

Diagnostic approach to acute renal failure

History and physical examination

The history and physical examination can provide invaluable clues that help determine whether the ARF

is a result of a prerenal, renal, or postrenal event. A careful review of the patient's past medical history, family history, medication use, trauma, and recent febrile illnesses is essential. Furthermore, a careful assessment of fluid intake and urine output can help to narrow the differential diagnosis as well as dictate future management. A major purpose of the physical examination in a patient with ARF is to attempt to determine the effective circulating volume. The patient's weight, blood pressure (sitting and standing), and pulse rate provide important clues. On general examination the patient must be carefully assessed for edema, state of hydration, pallor, petechiae, rashes, and abdominal signs of tenderness, bladder fullness, and visceromegaly. Careful cardiac and pulmonary examinations are performed to determine the degree of fluid overload. Clues for systemic diseases such as rash, jaundice, arthritis, or uveitis must always be looked for.

Urine studies

The urinalysis, urinary sediment, and urine indices are the most important factors in determining the cause of ARF. But these parameters must never be interpreted on their own; each value must be interpreted in relation to clinical findings and serum chemistry results. A high urine specific gravity (SG), in the absence of proteinuria, is suggestive of decreased effective circulatory volume and prerenal ARF. An inappropriately dilute SG suggests tubular injury or interstitial nephritis. A dipstick test that is >3+ positive for protein indicates intrinsic ARF with glomerular damage. Less proteinuria (<2+) may be seen in prerenal ARF, ATN, and postrenal ARF. Protein excretion >2 g/24 hours suggests glomerular injury. A positive urine dipstick for blood usually indicates hematuria. However, if there are no red blood cells (RBCs) on microscopic examination, myoglobinuria or hemoglobinuria must be considered. RBCs with RBC casts strongly suggest a glomerular lesion, especially in conjunction with significant proteinuria. WBCs and WBC casts are seen in pyelonephritis, acute postinfectious glomerulonephritis, and acute interstitial nephritis. Pigmented casts, granular casts, tubule epithelial cells and casts, and cellular debris characterize the urinary sediment in ischemic ATN.

Urine diagnostic indices, which are particularly helpful in characterizing ARF, include urine sodium and creatinine concentrations. When used in conjunction with the serum sodium and creatinine, the fractional excretion of sodium (FENa) can be calculated:

$$\text{FENa} = \frac{\text{urine}_{\text{Na}} \times \text{plasma}_{\text{Cr}}}{\text{plasma}_{\text{Na}} \times \text{urine}_{\text{Cr}}} \times 100$$

The results of the FENa, urine sodium, and urine osmolality can be used to differentiate between prerenal and intrinsic ARF. A low urinary sodium (<10 mmol/L) and a low FENa (<1%) indicate avid sodium and water retention. This is characteristic of prerenal ARF in which the intact proximal and distal tubules are able to respond appropriately to renal hypoperfusion. Conversely, the damaged tubules in ATN are unable to reabsorb sodium efficiently and this results in a high urine sodium concentration (>10 mmol/L) and an FENa of >2%. Two important caveats when using the FENa to assess ARF are underlying renal disease and the concurrent use of diuretics. In postrenal obstruction the indices are more variable and not very helpful. Early in the course of the disease they may resemble those of prerenal ARF, but as tubular damage progresses the indices become more similar to those of intrinsic ARF.[8,11]

Blood studies

Evaluation of the BUN and serum creatinine concentration is essential in making a diagnosis of ARF, but the serum electrolyte concentrations are more important guides for morbidity and mortality. The serum potassium concentration must be monitored closely in a patient with oliguria and, even more so, anuria. Life-threatening hyperkalemia, particularly in association with a metabolic acidosis, must be treated immediately. Hemoglobin, hematocrit, platelet count, and serum concentration of calcium, phosphorus, bicarbonate, and albumin must be routinely evaluated in patients with ARF. Serologic tests for streptococcal infection and complement studies are indicated if there are signs of AGN. It has traditionally been taught that a serum BUN:creatinine ratio of >20 suggests prerenal ARF, whereas the ratio is about 10 in ATN. Unfortunately, this ratio is affected by many factors, including a catabolic state and gastrointestinal bleeding, which negates its value in critically ill patients.[11]

Diagnostic imaging

The two most helpful initial imaging studies in patients with ARF are a chest radiograph and a renal ultrasound. Chest radiographs can help define whether there is significant cardiomegaly or pulmonary edema as a result of fluid overload. Renal

ultrasonography is extremely useful when either obstruction or RVT is suspected. Additionally, if it is unclear whether the patient has ARF or CRF, the ultrasound may be diagnostic. In patients with ARF, the kidneys are often large and swollen. Conversely, the kidneys in CRF are often small, scarred, or dysplastic. In both instances they lose the normal corticomedullary differentiation and are echogenic.

Renal biopsy

A percutaneous renal biopsy may be indicated in children with ARF if the cause is unknown or if there is any suspicion of a crescentic glomerulonephritis.

Complications of ARF

The major complications of ARF are either related to metabolic dysfunction or to fluid overload. Metabolic complications of ARF are hyperkalemia, metabolic acidosis, hypocalcemia, hyperphosphatemia, hyponatremia, and rarely uremia (Table 23.4). Hyperkalemia is the single most life-threatening complication of ARF. The hyperkalemia is the result of impaired tubular secretion, decreased filtration fraction, and extracellular shifts of potassium induced by acidosis. Peaked T waves are usually the first manifestation of cardiotoxicity followed by prolongation of the PR interval and widening of the QRS complex. Prompt treatment of hyperkalemia is required in order to prevent ventricular tachycardia or fibrillation. Uremia is characterized by mental status changes, evidence of serositis, and bleeding diathesis as a result of platelet dysfunction. It occurs when urea and other waste products build up in the tissues because the kidneys are unable to eliminate them adequately.

There are multiple causes for hypocalcemia in ARF, including hyperphosphatemia, decreased gastrointestinal calcium absorption, vitamin D deficiency, and parathyroid hormone (PTH) resistance. The most important acute reason is hyperphosphatemia. The hypocalcemia is usually mild and may cause tetany if markedly reduced. The hyperphosphatemia in ARF is the result of decreased renal excretion. Metabolic acidosis is very common in ARF. Declining renal function reduces the kidney's ability to excrete the net acids generated by the diet and to carry out normal metabolic function. Paradoxically, metabolic acidosis increases the fraction of serum calcium in the ionized form, which lessens the risk of hypocalcemia. Special attention must be paid to the serum ionized calcium concentration when correcting metabolic acidosis because tetany may ensue.

Table 23.4 Complications of acute renal failure

Fluid overload
Hypertension
Hyperkalemia
Hyponatremia
Metabolic acidosis
Hyperphosphatemia
Hypocalcemia
Hyperuricemia

Patients with oliguric or anuric ARF commonly present with hypervolemia and fluid overload. The hypertension is usually caused by fluid overload, but may also be the result of changes in vascular tone or activation of the renin–angiotensin system. If the fluid overload worsens, the patient may develop pulmonary edema and/or congestive heart failure.

Management of acute renal failure

There are five main principles in managing ARF:

1 Maintaining appropriate renal perfusion
2 Avoidance of nephrotoxic agents
3 Establishing fluid balance
4 Maintaining electrolyte and acid–base balance
5 Providing nutritional support

In almost all circumstances, with the important exception of glomerular nephritides, renal hypoperfusion is a predisposing factor to the development of ARF. Optimizing intravascular volume is a fundamental principle in preventing the development and progression of ARF. If children at risk for the development of ARF are adequately hydrated prior to a known incipient insult, the extent of the renal injury can often be decreased or even prevented. This is particularly important prior to the administration of contrast media, aminoglycosides, cisplatin, or amphotericin, and in preoperative patients. Additionally, it is important to stop or avoid medications that cause intrarenal afferent arteriole vasoconstriction (NSAIDs) or efferent arteriole vasodilation (ACE inhibitor). Even in well-hydrated patients, potential nephrotoxic agents should only be used when necessary and with special attention to dosing schedules and by monitoring serum concentrations.

Establishing fluid balance is perhaps the most challenging and critical step in managing ARF. Prerenal

ARF is the most common situation in which intrinsic renal damage can be prevented. Any hypovolemic patient who presents with oligoanuric ARF has a potential prerenal component. The first step in managing a patient with potential prerenal ARF is fluid resuscitation with one or more rapid infusions of normal saline, without any potassium, unless the patent is hypokalemic as a result of diarrhea or a tubulointerstitial disease. Maintenance fluids and replacement of ongoing losses should not be neglected during this period of initial rehydration. If the urine output does not increase after the patient is assessed to be euvolemic, intrinsic renal damage must be assumed. At this stage, in the absence of increased urine output, fluid restriction becomes essential to avoid hypertension, pulmonary edema, and congestive heart failure. During fluid restriction the patient should receive insensible losses (400 ml/m^2/24 hours of D5W) + urine output losses (milliliter per milliliter replacement with 0.45% NS). If the patient becomes hypervolemic after fluid resuscitation or requires large quantities of blood products or intravenous alimentation, a diuretic such as furosemide is administered in an attempt to increase urine output. Diuretics must be used with caution in the absence of good evidence of euvolemia or hypervolemia because they may worsen any prerenal component of the ARF. Patients who present with non-oliguric ARF (acute interstitial nephritis or the recovery phase of ATN) may actually be polyuric and require greater than normal volumes of fluid to avoid intravascular volume depletion.[12]

Maintaining the electrolyte and acid–base balance involves managing hyperkalemia, hypocalcemia, hyperphosphatemia, and metabolic acidosis. All potassium must be removed from the intravenous fluids in any patient with oligoanuric ARF. Treatment of hyperkalemia is indicated if electrocardiogram (ECG) abnormalities are noted or if serum concentrations are higher than 6–7 mEq/L. Treatment regimens are those that protect against hyperkalemia, those that redistribute potassium intracellularly, and those that remove potassium from the body.[8] Calcium gluconate, which is cardioprotective against the conduction abnormalities induced by hyperkalemia but does not remove potassium, is administered (0.5–1.0 mg/kg/dose) early in the course of treatment. Redistributive measures include albuterol, bicarbonate, and insulin + glucose infusions. All three interventions shift potassium intracellularly within 30 minutes; these are only temporizing measures and the serum potassium concentration may rise rapidly after they are discontinued. Potassium can be removed from the body via the gastrointestinal tract, the kidney, or by dialysis. Sodium polystyrene (Kayexalate), administered as 1 g/kg, exchanges sodium for potassium in the gastrointestinal tract and effects potassium removal. For every 1 g/kg of sodium polystyrene administered, the serum potassium decreases by 1 mmol/L. Hypernatremia is a side effect from excessive sodium absorption. If the patient is not anuric, loop diuretics are used to promote potassium losses by kaliuresis. Dialysis is the definitive therapy in patients who do not respond to these regimens.[8]

Hypocalcemia is usually mild and responds to correction of the hyperphosphatemia and dietary calcium supplementation. Intravenous calcium infusion is indicated if there is tetany or arrhythmia. Hyperphosphatemia is treated by dietary restriction and oral phosphate binders. Calcium carbonate and calcium acetate are well tolerated as phosphate binders when taken with meals. The treatment of the metabolic acidosis is important for maintaining a normal pH for optimal metabolism and for reducing the hyperkalemia. As previously mentioned, rapid correction of the acidosis can cause a precipitous decline in the serum concentration of ionized calcium. Oral sodium bicarbonate or sodium citrate tablets are given to correct the metabolic acidosis, but intravenous sodium bicarbonate is used for patients who have severe acidosis or who cannot take anything by mouth.

Nutritional support is essential because the patients are in a highly catabolic state. This is particularly challenging in oligoanuric patients who may be severely fluid restricted. Formula or parenteral nutrition should be concentrated whenever possible to provide maximum calories at a minimum volume. Children typically require only modest protein restriction (1–2 g/kg/day) and maintenance (or higher if catabolic) of non-protein calories. A low phosphorus and low potassium diet is also required. If adequate calories cannot be maintained because of fluid restriction, dialysis should be considered early in the course.[8]

Dialysis

The indications for initiating dialysis in ARF include:

1 Volume overload unresponsive to conservative management
2 Hyperkalemia, acidosis, or hypocalcemia unresponsive to medical therapy

3 Uremia (mental status changes, serositis, or bleeding diathesis)
4 Nutritional support

The patient's overall condition must be considered before making a decision to start dialysis. This is also important when selecting the appropriate type of dialysis. One important consideration is the patient's hemodynamic status. Hypotensive patients are poor candidates for hemodialysis but are often suitable for peritoneal dialysis or continuous renal replacement therapy (CRRT).[18] There are no precise criteria for selecting a particular dialysis modality, and practice patterns vary widely. However, CRRT is rapidly becoming the preferred modality for pediatric patients with ARF in the intensive care unit (ICU) setting.[19]

Conclusion

The prognosis for a child with ARF depends on the underlying cause, the length of insult, the number and type of other organs involved, the amount of residual urine output, and whether or not dialysis is required.[20] The major complications of ARF include fluid overload, hyperkalemia, metabolic acidosis, hyperphosphatemia, and hypocalcemia. Azotemia rarely produces uremic symptoms in the modern era. Judicious management of these complications can improve the morbidity and mortality associated with ARF in children. Immediate treatment of the underlying insult through fluid resuscitation in prerenal failure or relieving an acute obstruction in postrenal failure can prevent progression to intrinsic renal failure. Once intrinsic renal failure is established, it is essential to maintain adequate renal perfusion while avoiding further nephrotoxic insults whenever possible. If medical management fails to control the fluid and metabolic abnormalities, dialysis may be necessary. The choice of which dialysis modality to employ primarily depends on the hemodynamic status of the patient. Recovery from intrinsic renal disease also depends on the underlying cause of the ARF. Children with acute interstitial nephritis or ATN typically recover normal renal function and are at low risk for long-term morbidity. Conversely, children who lose a substantial number of nephrons, as occurs in HUS, cortical necrosis, or RPGN, are at risk for the development of CRF long after the initial insult. These children require lifelong monitoring of blood pressure, renal function, and urinalysis.

Renal transplantation

24

Nafisa Dharamsi, Curtis Sheldon, and Jens Goebel

Kidney transplantation is generally the therapy of choice for children with end-stage renal disease (ESRD) and has very few true contraindications (Table 24.1). For pediatric patients, this treatment modality offers special advantages with regards to growth and development,[1,2] in addition to the generally superior outcomes and cost-effectiveness of kidney transplantation as compared with chronic dialysis.[3,4] Patient as well as short- and mid-term graft survival have improved steadily over the past decades (Figure 24.1) due to ongoing advances in many areas related to transplantation, including the introduction of newer and more potent immunosuppressants. Accordingly, acute rejection rates within the first 12 months post-transplant are at an all-time low (Table 24.2). The improved graft survival has resulted in increasing recognition of several long-term complications affecting kidney transplant recipients, such as chronic allograft nephropathy (CAN), the high incidence of cardiovascular (CV) disease and malignancies, compared with the general population, post-transplant bone disease and non-compliance.[1,2] These complications, with special impact on pediatric patients because of their comparably longer life expectancy, represent the challenges faced by the transplant community in the years ahead.

Based on Organ Procurement and Transplantation Network data from January 2005, approximately 5% of all kidney transplant recipients are <18 years old.

Table 24.1 Contraindications to transplantation[a]

Malignancy
Chronic persistent infection
Recalcitrant non-compliance
Ongoing substance abuse
Severe irreversible extrarenal disease, including psychiatric illness
Absent insurance or equivalent coverage

[a] Contraindications are potentially modifiable – e.g. 'safe' time periods after curative treatment for malignancy are available in the literature; some centers offer kidney transplantation to certain patients infected with human immunodeficiency virus (HIV); non-compliance and substance abuse can be overcome in some instances; and financial coverage can eventually be established in many circumstances.

The causes of ESRD in these pediatric patients are substantially different from those in adults, as there is a preponderance of congenital obstructive and dysplastic conditions in pediatric patients and a virtual absence of diabetic or primary hypertensive nephropathy, the two most common causes of ESRD other than glomerular disease in adults (Table 24.3). Importantly, and as also shown in Table 24.3, failure of a previous renal allograft is the fourth most common indication for kidney transplantation both in children and adults. Lastly, there is an emerging additional group of individuals, including children, requiring treatment for chronic renal insufficiency (CRI) or ESRD: namely, recipients of non-kidney organ transplants who have developed renal dysfunction in large part related to chronic calcineurin inhibitor (CI) use.[5]

Urologic involvement in CRI care

The preponderance of primary urologic disease in children waiting for a kidney transplant explains why many of these patients will require pediatric urology services before, during, and after kidney transplantation. Early and aggressive management of CRI due to primary urologic disease may delay progression to ESRD and attenuate the adverse effects of uremia on growth and development. Elevated bladder pressures have specifically been shown to have a detrimental effect on upper tract function,[6] and upper tract deterioration in children with neurogenic bladders has been correlated with intravesical pressures >40 cmH_2O. This critical pressure threshold is associated with the onset of renal papillary morphologic distortion and intrarenal reflux of urine.[7–9] Such pressures can be documented using urodynamic studies with a focus on specific parameters, including compliance (pressure and volume), leak point pressures, voiding pressure, and postvoid residual urine (PVR).

The relationship between bladder dysfunction and deterioration of renal function is also illustrated in children with posterior urethral valves.[10] Figure 24.2 demonstrates the effect of age on bladder compliance in patients with ESRD that results from this disease. Urologic management of 'valve bladders' requires consideration of these maturational changes in function of these bladders. In young children, they tend to feature elevated pressures and low compliance, only to develop into larger-capacity, low-pressure reservoirs in older children. Medical management in this context is aimed at altering several parameters, including detrusor compliance and bladder emptying. Compliance can be altered by the administration of agents such as oxybutynin chloride or surgically by bladder augmentation. The detrusor pressure may be dramatically reduced for a given intravesical volume, but this may also result in an increase in PVR. In this persistently deleterious scenario, intermittent catheterization (IMC) will decrease PVR and lessen urinary stasis, thus reducing the risk for urinary tract infections (UTIs). In addition, IMC prevents pressure

Table 24.3 Most frequent indications for kidney transplantation in adults and children

increases during voiding. In older, and compliant, children, a less dramatic but often satisfactory improvement can also be obtained by frequent, e.g. 2 hourly, timed double voiding, with or without catheterization overnight.[11] A satisfactory working pressure range not only contributes to delaying the onset of ESRD but also ensures a safe receptacle for the allograft ureter if transplantation is needed.

Medical preparation of pediatric transplant recipients

The preparation of children for kidney transplantation is generally a multidisciplinary task shared by the patient's nephrology care team (e.g. nurses, dieticians, social workers, and nephrologists) and other services as needed (e.g. pediatric urology, surgery, psychiatry, anesthesiology, and critical care medicine). It cannot be emphasized enough how important it is to enable patients to enter the transplant procedure in as optimal a medical condition as possible. Specifically, children, like adults, with CRI or ESRD, should be encouraged to achieve and maintain physical fitness and weight control: CV fitness and absence of obesity will reduce surgical and anesthesthetic risks associated with the transplant operation and provide an advantage in the efforts to combat the increased risks for CV morbidity and excessive weight gain post-transplant.[12] Because transplanted children, especially once they are of school-age, do not uniformly display catch-up growth[1] (Figure 24.3), aggressive nutritional support is often required and, as indicated, growth hormone therapy needs to be considered before, and possibly after, transplantation.[13] Appropriate nutritional management pretransplant, frequently paired with the prescription of phosphate binders and active vitamin D and with regular monitoring of serum parathyroid hormone levels, will also attenuate post-transplant bone disease and thus increase the likelihood of appropriate growth.[14] Before transplantation, the recipients' up-to-date immunization status also needs to be ascertained, as no live vaccines can be given post-transplant and the response to other vaccines in the setting of immunosuppression may not be adequate.[15] Somewhat related, immunosuppressive therapy can lead to bothersome exacerbations of warts, and potential recipients should therefore have any warts dealt with as definitively as possible prior to transplantation.

In addition to these general principles, a number of issues need to be considered on an individual basis during preparation of the recipient. Psychosocial stability, both of the patient and the patient's family, is

of tremendous importance for adherence to the relatively complex treatment regimen required for good long-term results.[16] Such stability is largely defined individually for each patient/family unit and, accordingly, requires case-by-case interventions ranging from counseling over more intense psychological interventions all the way to the involvement of authorities dealing with complicated custodial situations. Before transplantation, patients and families also need to be educated about the need for frequent and comprehensive follow-up, especially during the first few months after hospital discharge. This need can create significant logistical obstacles with regards to transportation and caregivers' time away from work, and a number of families will benefit from support in planning for this challenging period ahead of time. As part of this planning effort, it should also be ensured that the patients will have appropriate coverage for their post-transplant medications and that they or their caregivers know, in particular, how to obtain the required immunosuppressive drugs in the outpatient setting. Depending on the recipient's developmental and pre-transplant medical (e.g. dialysis) status, plans are also necessary regarding vascular and gastrointestinal (GI) tract access. A central line may be needed for a prolonged period of time post-transplant to facilitate frequent blood sampling in very young recipients, those with very limited peripheral venepuncture sites, in patients who may need pre- and post-transplant plasmapheresis for immunologic reasons (see below), or because they are considered to be at high risk for the recurrence of focal segmental glomerulosclerosis.[17] A gastrostomy tube is essential in patients who require supplementation of additional nutrition or fluid or are unable to take all their post-transplant medications by mouth. Lastly, there is a subgroup of patients at increased immunologic risk from a previous kidney or other organ transplant, from blood transfusions, or from other sensitizing events. These individuals will benefit from specialized immunologic characterization and consequently from consideration of desensitization strategies prior to transplantation to enhance their potential for long-term graft survival.[18,19]

Prior to actual transplantation, a risk assessment of the recipient for thrombotic complications is also important, as graft thrombosis is a significant cause of pediatric transplant loss.[20,21] Risk factors include hypercoagulopathy (e.g. as seen in chronic nephrotic states), antiphospholipid antibodies (seen in 30–50% of patients with systemic lupus erythematosus), prior thrombosis of a large vein postoperatively (e.g. a renal transplant vein), or thrombosis associated with vascular access (e.g. for dialysis).[22] Accordingly, hypercoagulability should be corrected before the actual transplant procedure whenever possible. Alternatively, consideration needs to be given to the prescription of anticoagulation during and after the transplant, although controversy exists regarding the routine use of heparin in the perioperative period to reduce the incidence of renal allograft thrombosis. A recent retrospective study showed that young recipient age, young donor age, and increased cold ischemia time were associated with a higher risk for graft thrombosis, but the administration of heparin did not decrease the incidence of early renal allograft thrombosis.[23]

Urologic pre-transplant interventions

Pediatric kidney transplant candidates with underlying urologic disease are assessed with special attention to optimization of the urinary bladder or its substitute, for urinary tract reconstruction, and for possible pre-transplant nephrectomy (see below). If a significant symptom complex or urodynamic abnormalities are present, an attempt is indicated to achieve bladder control with a voiding regimen, anticholinergic therapy, and/or IMC. If voiding cannot be evaluated because of urinary diversion, pretransplantation urinary undiversion can be an invaluable tool to help ensure adequate bladder function.[24] If a bladder cannot be adequately addressed because of oliguria or the presence of diversion, bladder cycling via IMC may help ensure transplant candidacy, and complex bladder pathology associated with ESRD may require extensive reconstruction, including augmentation. In general, however, an attempt is made to avoid this procedure in valve patients, although some younger patients with this diagnosis have required pretransplantation augmentation.

Structural bladder abnormalities may be further characterized pretransplant by cystourethroscopy to clarify whether surgical intervention e.g. lower urinary tract reconstruction, is required. Aggressive bladder management post-transplant may improve renal allograft survival and function,[25–27] as decreased allograft success may be secondary to urinary stasis and not simply due to a distorted bladder.[28]

Table 24.4 outlines the indications for pretransplant nephrectomy.[6,29–32] Persistent proteinuria originating from the native kidneys is considered an indication for native nephrectomies, not only because such proteinuria can cause diagnostic uncertainty post-transplant but also because significant, i.e.

Table 24.4 Indications for pretransplantation native nephrectomy

Chronic renal parenchymal infection
Infected urolithiasis
Heavy proteinuria
Intractable hypertension
Polycystic disease
Acquired renal cystic disease
Infected reflux
Infected hydronephrosis

nephrotic-range, proteinuria at the time of transplantation is associated with an increased risk for thrombotic and infectious complications. In children with congenital nephrotic syndrome, nephrectomies are oftentimes performed at some point during their CRI stage to eliminate substantial protein losses. Otherwise, the native nephrectomies can be carried out several weeks before transplantation to allow resolution of the nephrotic state.[10,31–33] A similar approach should be considered for older children with focal segmental glomerulosclerosis with persistent proteinuria. Malignant degeneration in the pediatric age range has also been reported,[34] but this possibility needs to be weighed against the risks associated with native nephrectomies when preparing children for kidney transplantation.

Several strategic considerations regarding nephrectomy are relevant. Even in advanced CRI and ESRD requiring dialysis, some native kidneys excrete substantial amounts of urine, often allowing easier blood pressure control and less day-to-day restrictions with regards to fluid intake. Consequently, if only one kidney requires removal, this can be done at the time of transplantation and possibly through the same incision as the transplant itself. If both kidneys need to be removed, differential function can be analyzed by isotope imaging and the worst kidney removed pretransplant, with the other being removed at the time of transplantation. Exceptions to this approach include the presence of renal-mediated diseases (e.g. intractable infection or hypertension), space-related issues (as seen with polycystic kidneys), or significantly surgically altered kidneys (e.g. diversion), all of which may make nephrectomy at the time of transplantation too difficult, requiring a more staged approach.

The nephrectomy incision should be positioned so as not to interfere with abdominal wall blood supply, as a subsequent transplant incision may result in sacrifice of the inferior epigastric vessels. If this has been performed bilaterally and previous ligation of the superior epigastric vessels has been done, compromised healing or even abdominal wall necrosis may therefore be encountered. Accordingly, transverse upper abdominal incisions (e.g. for bilateral native nephrectomies) should be avoided.

Bladder augmentation procedures may be necessary before renal transplantation to ensure a low-pressure urinary reservoir, because a relationship between high intravesical pressures and renal, including renal transplant, deterioration is well established (see above).[26,27,35–38] On the other hand, effective management of dysfunctional bladders is associated with long-term allograft survival comparable to that seen in recipients with normal bladders.[39,40] Since augmentation in the transplant setting can complicate the overall clinical course, it should only be performed in carefully selected patients with a clear need for this procedure. In Table 24.5, various types of bladder augmentation are reviewed. Although ileocystoplasty is the most prevalent procedure because of its ease of use, its disadvantages include significant mucus production, bladder calculus formation, and metabolic acidosis. These disadvantages are overcome by performing a gastrocystoplasty, but this approach is not a panacea either.[41]

In selected circumstances, bladder augmentation in the form of autoaugmentation or ureterocystoplasty can be performed extraperitoneally, as can the creation of a Mitrofanoff neourethra (Figure 24.4). If

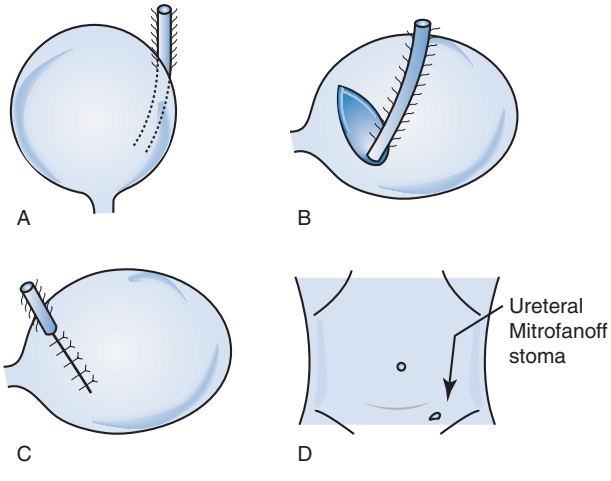

Figure 24.4 Retroperitoneal creation of a ureteral Mitrofanoff conduit. A, Ureter is mobilized with preservation of the adjacent vascular supply. Nephrectomy is performed (dorsal lumbotomy or flank incision). B, Detrusor incision is made and a mucosal trough developed. C, Detrusor flaps are approximated over the ureter. D, Final position of the Mitrofanoff stoma does not interfere with subsequent transplantation.

Table 24.5 Factors to consider in bladder augmentation

None	Low risk of complication	Renal injury if bladder non-compliant	Whenever possible
Autoaugmentation	No metabolic consequences May be performed extraperitoneally	Augmentation surface not amenable to ureteral or MNU implantation Risk of perforation Limited clinical experience	Sufficient native bladder surface for implantation Near-normal bladder capacity
Ureterocystoplasty	No metabolic consequences May be performed extraperitoneally	Augmentation surface not amenable to ureteral or MNU implantation Requires presence of large dilated ureter	Sufficient native bladder surface for implantation
Seromuscular augmentation	No metabolic consequences	Augmentation surface less amenable to ureteral or MNU implantation	Sufficient native bladder surface for implantation Near-normal bladder capacity
Ileocystoplasty	Technically simple	Augmentation surface less amenable to ureteral or MNU implantation Acidosis, mucus, or infection	Sufficient native bladder surface for implantation Stomach unavailable
Colocystoplasty	Technically simple Ureteral or MNU implantation possible	Acidosis, mucus, or infection	Stomach unavailable
Gastrocystoplasty	Avoids acidosis, mucus, or infection Ureteral or MNU implantation	Hematuria/dysuria syndrome readily performed Rare–alkalosis	Wide application

MNU, Mitrofanoff neourethra.

transperitoneal reconstruction is required before transplantation, this should be done when the patient is ready for listing or 6–12 weeks before scheduled living donor transplantation, with the patient maintained on hemodialysis in the interim.

The management of vesicoureteral reflux (VUR) in the native retained renal unit remains controversial. An increased incidence of acute symptomatic UTIs in patients with continued native VUR has been demonstrated compared with controls and with patients with previously corrected reflux,[42,43] although other studies have not confirmed this.[44] The consensus is that VUR associated with persistent or recurrent infection should be managed by ureteral reimplantation or nephroureterectomy. Reimplantation is preferable in order to preserve the native ureter, and is thus an additional option for the management of possible ureteral complications of future allografts. Additionally, higher-grade sterile reflux associated with ureteral dilation has been associated with sufficient morbidity to justify pretransplantation ureteral reimplantation,[42] with a pretransplant nephrectomy as an alternative.

In general, a key element in the surgical care of the transplant patient involves preservation of the peritoneal cavity whenever possible to allow effective peritoneal dialysis. An effort should therefore be made to avoid transperitoneal surgery, which may compromise effective exchange of dialysate secondary to postsurgical adhesions. In addition, even serosal changes can interfere with effective ultrafiltration and thus obviate peritoneal dialysis.

Timing of transplantation

Whereas the occurrence of an organ transplant from a deceased donor is largely unpredictable, transplantation can be scheduled in advance when a live donor is available. Once a transplant date is set, arrangements can also

be made to initiate immunosuppressive therapy ahead of time, typically several days pretransplant at those centers choosing this approach, to facilitate therapeutic drug levels at the actual time of surgery. It should be noted, however, that data supporting this practice as a means to improve outcome are not available.[45]

Live donor transplantation allows the performance of a pre-emptive transplant, i.e. transplantation just before dialysis needs to be initiated. Pre-emptive transplantation has a number of advantages[46] and should thus be considered whenever possible. In the setting of pre-emptive transplantation, especially when an adult kidney is placed into a small child, caution with pretransplant immunosuppression should be exercised as these recipients can be quite uremic, and treatment with a CI for a number of days before transplantation may worsen this condition further. Under these circumstances, a grafted adult kidney that functions immediately can remove uremic toxins at a staggering rate and thus create a clinical scenario similar to the dysequilibrium syndrome seen in the setting of zealous, typically first-time, hemodialysis.

Renal allografts can either be obtained from a deceased donor or a living donor, and superior outcomes have been documented for the latter when adjusted for the degree of human leukocyte antigen (HLA) matching.[47,48] However, it should be noted that at least for the first several years post-transplant, North American first-time pediatric recipients of deceased donor kidneys now have essentially equivalent graft survival to those of live donor kidneys (Table 24.6). This phenomenon is probably multifactorial and, paired with the special advantages for pediatric patients with regards to growth and development associated with transplantation versus dialysis, supports the preferential waitlisting practices afforded to children as opposed to adults in North America and elsewhere, especially since children represent such a diminutively small fraction of the entire population of patients with ESRD. While efforts are ongoing to refine organ selection criteria for children, a useful rule of thumb is that the best kidney for a child is one from an otherwise healthy teenage or young adult donor and that a single kidney from a very young pediatric donor will not provide acceptable long-term function.[49] Under selected circumstances, however, consideration can be given to the transplantation of an en bloc pair of kidneys from such a very young donor into a pediatric recipient.[50] Similarly, the use of kidneys from deceased donors meeting expanded criteria or even from non-heart-beating donors, which is gaining increasing ground in adult kidney transplantation, is currently only indicated for children in extremely rare situations because these organs are unlikely to provide the very long graft survival desired especially for pediatric recipients.

Table 24.6 Similar 1-year graft survival rates in living and deceased donor kidney transplantation for pediatric recipients

Transplant year	Living donor	Cadaver
1987–1990	89.4%	75.2%
1991–1994	91.8%	85.0%
1995–1998	93.9%	90.4%
1999–2003	95.3%	92.3%

The transplant

Deceased donor management

The optimal medical management of individuals who have died and become organ donors is evolving continuously, and a comprehensive review of this topic has recently been published.[51] Typically, specialized professionals from the local organ procurement organization are closely involved in this part of the donor care to ascertain optimal organ quality at the time of retrieval.

This retrieval is performed through a midline incision extending from the sternal notch to the pubis.[52,53] The intestines are mobilized and the distal aorta and inferior vena cava isolated. As necessary, the vascular anatomy of the liver, pancreas, and small intestine is defined and the aorta isolated at the level of its diaphragmatic hiatus. The distal aorta is cannulated, the supraceliac aorta clamped, venous drainage achieved (generally at the level of the right atrium), the aorta flushed with cold preservation solution, and the abdomen packed with sterile saline ice slush. Organs are sequentially removed, beginning with the heart, followed by the lungs, liver, small intestine, or pancreas, and finally, the kidneys. The kidneys are removed en bloc with the adjacent aorta and vena cava and the ureters divided at the level of the urinary bladder. Kidneys from very young donors are not separated until a decision has been made about whether or not they will be transplanted individually or en bloc. Otherwise, the kidneys are separated on the back table and cold-stored for distribution.

From Ryckman.[52]

Organ preservation solutions are designed to minimize hypoxia- and hypothermia-induced injury. The active ingredients of the two most widely used solutions are outlined in Table 24.7.[52,53] A comparison of both solutions has revealed a significant benefit in graft function and survival favoring University of Wisconsin solution over EuroCollins solution.[54] The osmotic swelling and sodium pump paralysis associated with hypothermia are compensated by the elimination or reduction of chloride, whose intracellular shift facilitates osmotic edema, in favor of impermeable ionic agents such as phosphate, sulfate, and lactobionate. Lactobionate, raffinose, hydroxyethyl starch, and mannitol further contribute to reducing intercellular swelling. Intracellular acidosis is compensated by the avoidance of glucose and the addition of phosphate, which acts as a hydrogen ion buffer. Oxygen free radical-induced reperfusion injury is compensated by allopurinol and glutathione, and the depletion of high-energy phosphate compounds is countered by the addition of adenosine.

Live donor management

In part because of the ever-worsening relative shortage of deceased donors, the majority of pediatric recipients in North America currently receive a kidney from a live donor, and most live donors for these children are their parents (NAPRTCS 2004 Annual Report). This poses unique challenges and responsibilities on the centers caring for these families. Despite the now well-recognized short- and long-term risks associated with being a live donor,[55] parents may feel a special duty to donate one of their kidneys to their child, even if they jeopardize their own health. The issue of organ donation needs to be approached with sensitivity, and full disclosure and discussion of all relevant information in a family-centered setting is important. Specific strategies to consider include, but are not limited to, the provision of written educational material from center-independent resources like the United Network for Organ Sharing (http://www.unos.org), the performance of a parent's medical evaluation as a potential donor (Table 24.8) by an independent, critical physician otherwise dissociated from the transplant center, the facilitation of contacts between the potential donors and past donors who have had difficult experiences related to their donation, and possibly the identification of a donor advocate or the creation of a donor advocacy board somewhat similar to an ethics committee.

Furthermore, individuals who have been cleared for living donation need to be re-evaluated periodically for new or worsened conditions possibly jeopardizing their donor status if the planned transplant does not take place within a reasonable period of time, i.e. 6–12 months, either because of a stabilization in the recipient's health status or because of new medical or non-medical issues related to the recipient requiring postponement of the procedure.

This scrutiny in donor selection is particularly important when an individual who is not biologically, but emotionally, related to the potential recipient steps forward as a willing donor, or if an altruistic donor is found.[56] Local allocation practices of organs from such altruistic donors vary, but preference is sometimes given to children waitlisted for a deceased donor kidney. Generally, an in-depth psychological assessment of these donors is required to exclude hidden non-altruistic motives or other circumstances making donation unadvisable.

Another novel concept aiming to attenuate the deceased donor shortage and to specifically overcome the obstacles posed by blood type incompatibilities and presensitization is the creation of live donor exchange programs. Such programs have been established in several regions of the United States and are beginning to provide relief for recipients whose chances of receiving a suitable kidney graft would otherwise be slim.[56]

Table 24.8 Suggested evaluation of living donor candidates

Evaluation	Possible exclusion criteria
Initial screening	
History	Younger than legal age of consent, diabetes mellitus, marked obesity, significant cardiovascular or pulmonary disease, substance abuse, malignancy, transmissible infection
Blood typing	ABO incompatibility
Tissue typing and crossmatch	Positive crossmatch
Physical examination	see 'History' above
Psychological evaluation	Evidence of coercion, reluctance to donate
Pregnancy test in females	Positive test
Secondary screening	
Laboratory studies (complete blood count, coagulation studies, fasting glucose and cholesterol, electrolytes, liver enzymes, albumin/total protein, uric acid)	Significant uncorrectable abnormality
Renal assessment (urinalysis, serum creatinine and blood urea nitrogen, creatinine clearance, protein excretion, renal ultrasound, renal arteriography	Renal disease Complex abnormality of renal anatomy, e.g. vasculature
Chest radiograph	Significant pulmonary pathology
Screening for infection (cytomegalovirus, Epstein–Barr virus, and human immunodeficiency virus titers, hepatitis B and C serologies, purified protein derivative, urine culture)	Transmissible chronic infection
Pelvic examination with *Pap smear* and, if >40 years, *mammography* within 1 year in females	Malignancy
Rectal examination and, if >40 years, *prostate-specific antigen* in men	Malignancy
Tertiary screening	
For family history of diabetes or borderline fasting glucose: 2-hour postprandial glucose, glycosylated hemoglobin, oral glucose tolerance test	Diabetes mellitus
For older donor age, cardiac risk factors or symptoms: non-invasive stress testing, echocardiography	Significant cardiac disease
For pulmonary symptoms: pulmonary function tests	Significant pulmonary disease
Additional screening	
If scheduled transplant is postponed: Periodic re-evaluation for changes in donor health status	New significant medical problems

Living donor nephrectomy is performed simultaneously with the surgical exposure of the recipient. Antiembolism sequential compression stockings are used, and the patient is placed in a flank position. Traditionally, live donor nephrectomy has been performed through an extended 11th or 12th rib incision, which enables excellent retroperitoneal exposure of the renal hilar vessels and the ureter. The kidney is gently mobilized, taking care to avoid excessive dissection of the lower pole, so as to maintain ureteral blood supply. In addition, the ureter is mobilized with a generous cuff of retroperitoneal adipose tissue in order to maximize its vascularity. The hilar vessels are dissected to their junction with the aorta and vena cava.

When the recipient room is ready, the donor ureter is divided as far distally as possible and the distal

ureteral stump ligated with absorbable suture material. Good urine output is documented from both the divided ureter and the indwelling urethral catheter. The renal artery and vein are clamped proximally, the vessels divided, and the kidney immediately flushed with cold preservation solution, placed in saline ice slush, and delivered to the adjacent recipient room, while the renal artery and vein stumps are oversewn with Prolene suture. Although significant morbidity and mortality have been low with this approach, postoperative discomfort, as well as length of recovery and associated time off work, may be significant and have in some instances served as a deterrent to donation.

Accordingly, encouraging early results have been reported with the use of laparoscopic live donor nephrectomies: e.g. decreased analgesic requirements, decreased length of hospital stay, and an earlier return to work.[57–61] However, recent data suggest that small pediatric recipients of adult kidneys removed laparoscopically may be at risk for inferior outcomes: i.e. delayed graft function and early rejection.[62] A relatively low threshold for open donor nephrectomy in these situations therefore seems advisable until more data are available.[63]

Recipient management

As mentioned above, recipients entering the operating room for a kidney transplant should be in their best possible medical condition. Moreover, children on dialysis may undergo hemodialysis on the day or peritoneal dialysis the night before their transplant for metabolic control (e.g. to reduce serum concentrations of potassium or blood urea nitrogen), but they should be relatively volume-loaded to facilitate adequate perfusion of the new allograft.[64] Therefore, dialysis immediately pretransplant should be performed with an adjusted ultrafiltration goal, possibly requiring an increase in antihypertensive drug therapy to compensate for this adjustment. If hemodialysis is required on the day of transplantation, anticoagulation should also be used sparingly or not at all to avoid an increased risk of bleeding during surgery.

The transplantation process in the recipient begins with the induction of general endotracheal anesthesia. The patient is positioned supine, a Foley catheter is placed, and the bladder is inflated with an antibacterial solution. Other potential lines include an arterial line, central venous access and, rarely, a pulmonary arterial catheter. A second-generation cephalosporin is administered and intravenous hydration undertaken. Red blood cell mass is expanded if indicated, but care should be taken to avoid possible sensitization.

The operation is performed through a 'hockey-stick' incision to give excellent retroperitoneal exposure. An attempt is made to place the kidney retroperitoneal in order to preserve the peritoneal cavity for future dialysis access if needed. Typically, grafts are readily placed retroperitoneal in recipients weighing >20 kg and in those weighing between 10 and 20 kg and receiving a pediatric or small adult kidney. Transabdominal placement through a midline incision is considered in recipients weighing <10 kg (Figure 24.5)[65] due to the limited volume of the retroperitoneum. However, these anatomic decisions need to be made on an individualized basis.

The venous and arterial trees for the anastomotic sites are carefully mobilized with division of the overlying lymphatic vessels between ligatures. In general,

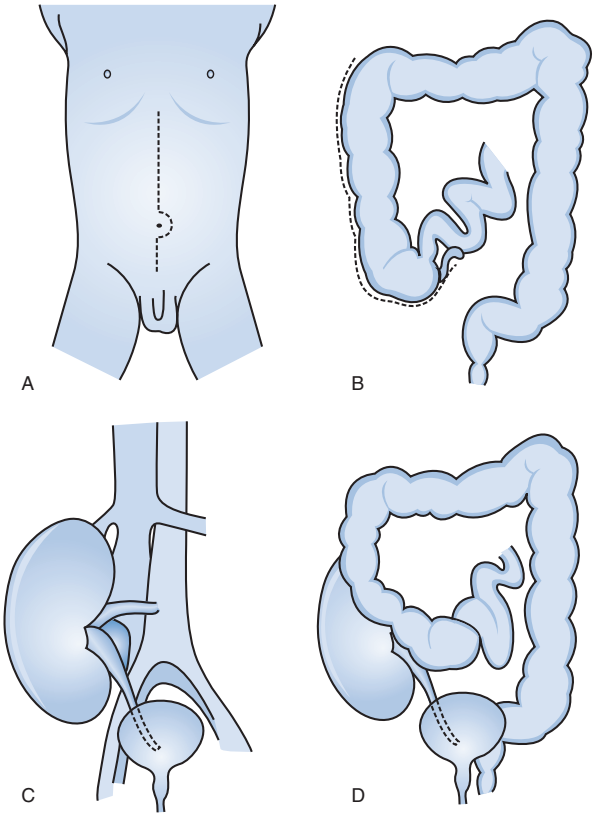

Figure 24.5 Transperitoneal approach to renal transplantation in the infant. A, Midline abdominal incision. B, Reflection of right colon to expose retroperitoneum. C, Renal vessels anastomosed to aorta and inferior vena cava; ureter reimplanted in bladder. D, Right colon repositioned to allow exposure of the lower pole of the graft. (Reproduced with permission from Sheldon et al.[66])

the anastomosis is placed at the level of the aorta or aortoiliac junction in infants and toddlers, in the common iliac artery in young children, and in the external iliac artery in adolescents and young adults. Once vascular control is achieved, the venotomy is made, the recipient vein injected with a heparin–saline solution, and the anastomosis is completed. The arteriotomy is then made, and the arterial anastomosis is then performed. If the aorta is to be occluded, the patient is treated with heparin. Mannitol (0.5 mg/kg) and furosemide (0.5–1 mg/kg) are administered before completing the anastomoses. The vascular clamps are removed, with gentle pressure applied to the renal artery to allow clearance of any debris or air pockets before kidney revascularization. An intra-arterial injection of verapamil (0.1 mg/kg, not exceeding 5 mg, into the upstream recipient artery with the distal recipient artery still occluded) may be performed at this time.

Post-transplantation hypotension in the recipient is a major risk factor for allograft loss and must be aggressively avoided. Given this, the blood volume of the patient is expanded to a central venous pressure (CVP) of 12–16 cmH_2O, with the expectation that vascularization of an adult allograft will result in the acute sequestration of approximately 250–300 ml of blood from the general circulation. Failure to achieve adequate renal turgor may necessitate additional volume expansion or the addition of inotropic support, e.g. a low-dose dopamine infusion. Especially for small recipients of an adult kidney, the generous volume requirements to maintain a CVP sufficient for good blood flow to the transplant persist during and after the surgery, thus requiring special attention by anesthesia and by the management team providing recipient care immediately post-transplant.[64] Even long-term, generous fluid administration, possibly including night-time or bolus supplementations, e.g. via G-buttons, has been advocated.[64]

Variations in vascular anatomy may obviate the use of a kidney from a prospective living donor or may create reconstructive challenges in the cadaveric allograft.[66] As previously outlined, in cadaveric renal procurement, the kidneys are removed en bloc with the adjacent vena cava and aorta (Figure 24.6A). Here, the kidneys are visualized from a posterior perspective and the aorta opened in the midline posteriorly. This is followed by division of the anterior aorta and the vena cava, again in the midline. The kidney is thereby provided with an adjacent segment of both aorta and vena cava, which gives reconstructive flexibility. As demonstrated in Figure 24.6B, a renal vessel of good

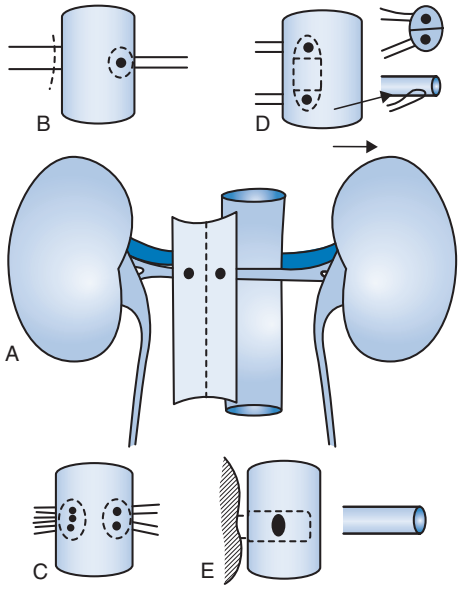

Figure 24.6 Management of variations in renal vascular anatomy. (Adapted with permission from Sheldon et al.[66])

dimension can be divided, spatulated, and anastomosed. If the vessel is small, it may be prepared with a small patch of adjacent aorta or vena cava to facilitate the anastomosis and minimize the risk of anastomotic stenosis or thrombosis. Multiple vessels entering the vena cava or aorta in a cluster may be prepared on a single large cuff of aorta or vena cava. If multiple vessels are encountered that enter the vena cava or aorta at sites remote from each other, reconstruction may be needed (see Figures 24.6C and D). If both vessels are particularly modest in size, two small patches may be anastomosed to create one larger cuff for anastomosis. If a dominant artery is encountered with a second smaller artery, an end-to-side anastomosis is undertaken. This type of vascular reconfiguration is enhanced by the use of an operative microscope.[67] Occasionally, an extremely short renal vein is encountered. Usually, generous mobilization of the recipient venous tree is sufficient to enable a tension-free anastomosis. When this is not possible or is insufficient, the renal vein may be extended by tubularizing adjacent flaps of vena cava (Fig. 24.6E).

Ureteral implantation is most commonly performed into the bladder. Recently, however, investigators have reported ureteroureteral anastomosis as another option in pediatric renal transplantation.[68] Ureterovesical reimplantation may be performed either transvesically (Paquin's method) or extravesically (detrusorrhaphy). Advantages of the extravesical approach (Figure 24.7)

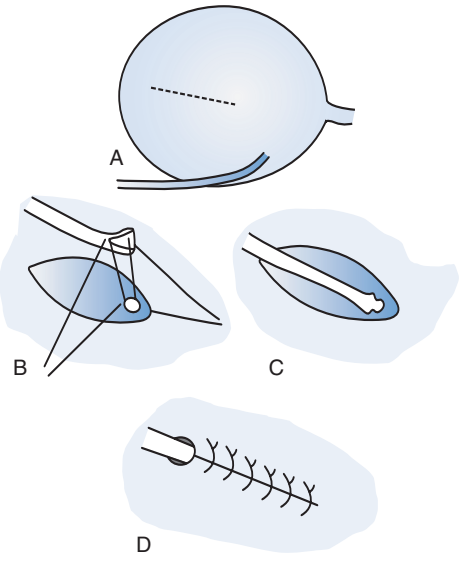

Figure 24.7 Technique for extravesical ureteral implantation.

include a shortened operating time, a very low incidence of anastomotic obstruction, and most importantly, a dramatic reduction of postoperative hematuria and urinary extravasation. This is particularly advantageous in the young recipient whose urethra only allows a small-caliber catheter. Ureteral implantation is considerably more critical in the child, as the incidence of dysfunctional voiding pathophysiology is particularly high in this age group. An attempt is made to place the anastomosis somewhat lateral on the bladder, where the bladder wall is less mobile, and a ureteral tunnel length-to-ureteral diameter ratio of 4:1 is sought (see Figure 24.7A). The detrusor is incised and a plane developed between the detrusor and the underlying bladder uroepithelium. A small defect is created distally in this mucosal trough, and a spatulated anastomosis is performed (Figure 24.7B). The ureter is advanced distally with the first suture placed (Figures 24.7C and D). Because ureteral obstruction (e.g. from anastomotic edema) or extravasation represent potentially devastating complications, an internal indwelling stent is often advantageous in the early postoperative period. This stent can then be removed several weeks post-transplant, oftentimes combined with removal of chronic dialysis access.

Postoperative care

In addition to general perioperative care, including circulatory, respiratory, and nutritional support, postoperative care of the pediatric transplant recipient includes immunosuppression and careful fluid and electrolyte management. The latter involves replacing insensible losses and urine output, initially on a volume-for-volume basis and with close attention to the patient's electrolyte status. The freshly transplanted kidney is often unable to concentrate the urine, so that urine output may be tremendous in the first several postoperative days.

Generally, immunosuppressive therapy is in constant evolution to achieve the best possible antirejection prophylaxis without an unacceptably high incidence of overimmunosuppression or other drug-related toxicities.[69] In this context, it has become quite clear that immunosuppressive protocols cannot be administered in a 'one size fits all' fashion: first-time Caucasian recipients of a live donor kidney who have no evidence of presensitization appear to require less powerful antirejection prophylaxis than recipients of a repeat transplant, especially one from a deceased donor, recipients with evidence of presensitization, or African-American recipients.[70] Additionally, the recent discovery of genetic polymorphisms and related phenomena affecting drug metabolism and exposure[71,72] and immunologic responsiveness[73] further undermines the concept of a unified immunosuppressive approach. It therefore likely behooves transplant programs to adapt flexible immunosuppression protocols that can be tailored to each recipient's perceived risk profile. Theoretically, the development of such protocols is augmented by sufficiently powered multicenter studies, but in view of the relatively small number of pediatric kidney transplants performed at any given time and given the increasing number of drugs and drug combinations available, such studies are quite difficult to set up and perform. Additional guidance in the selection of pediatric immunosuppressive regimens is therefore also derived from adult studies and from local practice and experience. A typical protocol to be used initially in pediatric kidney transplantation currently consists of triple therapy with a CI, an antiproliferative agent, and steroids, possibly paired with a course of induction with a non-depleting anti-T cell antibody (Table 24.9). The doses and target levels of these agents are geared towards the recipient's estimated risk for acute rejection, balanced against side effects and other potential disadvantages associated with the use of these agents. Of note, recent efforts by a variety of groups have further broadened the available choices for initial immunosuppression. They now include complete steroid avoidance, induction with alterna-

Table 24.9 Typical immunosuppression protocol for pediatric kidney transplant recipients

Induction[a]	Maintenance[b]
Consider non-depleting anti-T cell antibody	
High-dose steroids	Tapered steroids
Calcineurin inhibitor (CI), e.g. tacrolimus	Modest-dose CI
Antimetabolite, e.g. mycophenolate mofetil	Mycophenolate mofetil

[a] For first several weeks and months post-transplant.
[b] An inhibitor of the mammalian target of rapamycin (mTOR), such as sirolimus (rapamycin) or everolimus, can be added or substituted for any one of the three maintenance agents based on center practice.

tive antibody preparations, and introduction of a new class of maintenance immunosuppressants, the inhibitors of the mammalian target of rapamycin (mTOR), largely to reduce the use of CIs, which carries a substantial long-term risk of nephrotoxicity.[69,74]

Hypertension frequently occurs or, if pre-existing, worsens in the immediate post-transplant setting for several reasons, including liberal fluid management (see above) and treatment with high doses of corticosteroids. Whereas mild blood pressure elevations above the patient's pre-transplant range may even be temporarily desirable to enhance perfusion of the new allograft, more pronounced hypertension, especially if it is causing symptoms, should be treated expeditiously. In this setting, calcium channel antagonists are particularly safe and effective, although attention needs to be paid to the interference of some of these agents, particularly verapamil, diltiazem, amlodipine, and nicardipine, with CI metabolism.[70] Once transplant function has stabilized, the same group of agents may also be particularly beneficial,[75,76] although angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) should also be considered, especially if there is evidence of CAN.[77,78]

Hypophosphatemia and hypomagnesemia can occur quickly post-transplant: the former is largely due to 'hungry bones' in the presence of a well-functioning kidney and frequently requires phosphorus supplementation for several months; the latter is associated with CI therapy especially tacrolimus, and may also require supplementation, especially if clinical symptoms of hypomagnesemia are present.

Infection prophylaxis against bacterial, viral, and fungal pathogens is part of essentially all routine post-transplant medication regimens. Antibiotic coverage is typically provided perioperatively to prevent wound infections and then transitioned to a prophylactic regimen against UTIs and *Pneumocystis carinii*. Specific guidelines have been developed for antiviral prophylaxis in the post-transplant setting.[79] This antiviral prophylaxis is largely directed against cytomegalovirus (CMV) and usually prescribed based on each patient's risk profile, as determined by the recipient's as well as the donor's history of CMV exposure and by the strength of immunosuppression used. Unfortunately, no convincingly effective prophylactic regimens are currently available for the prevention of Epstein–Barr virus (EBV) infection. Since many pediatric transplant recipients are EBV-naïve and many adult donors carry EBV, primary EBV infection of transplanted children via the graft is a considerable problem, especially because EBV can drive the development of post-transplant lymphoproliferative disorder (PTLD).[80] Lastly, antifungal prophylaxis is typically provided during the first several months post-transplant, i.e. while the degree of immunosuppression prescribed is considerable. Accordingly, a number of centers also 'recycle' the full spectrum of infection prophylaxis during and after episodes of acute rejection, requiring enhanced immunosuppressive therapy.

Gastrointestinal prophylaxis against steroid-associated gastritis and ulcer disease is typically given in the form of a histamine H_2 receptor blocker. At our center, recipients are tried off these agents once they are taking all their medicines by mouth and if they are free of gastrointestinal complaints.

Approach to early graft dysfunction and other complications

Graft dysfunction immediately post-transplant is suggested by lack or decrease of urine output and by absence of the expected decrease in serum creatinine. Initial non-function, i.e. the complete absence of urine production, is very concerning as it could be caused by thrombotic obstruction of arterial blood flow to the graft. Accordingly, initial non-function requires immediate diagnostic evaluation and subsequent correction if the transplant is to be salvaged. Many centers therefore perform a Doppler ultrasonographic evaluation or a nuclear scan of the transplant immediately after skin closure or upon arrival in the

postoperative care unit, at least if there is no sufficient urine output attributable to the transplant. Along these lines, many recipients still have their native, oftentimes urine-producing, kidneys at the time of transplantation, making interpretation of urine output immediately post-transplant challenging at times. If blood flow to the transplant is adequate, acute tubular necrosis should be suspected as an alternative cause of initial non-function, especially in deceased donor transplants. In recipients who are not at particularly increased immunologic risk, hyperacute rejection is very unlikely. Lastly, the possibility of complete urinary tract obstruction needs to be excluded by ultrasound in this scenario.

In grafts with initially acceptable urine production but a subsequent decrease in output, additional possibilities need to be considered. These include low intravascular volume, rejection, and acute CI toxicity. Low intravascular volume can be diagnosed if a fluid challenge sufficient to raise CVP results in restitution of adequate diuresis, and acute CI toxicity is indicated by elevated trough levels, e.g. tacrolimus concentrations >20 ng/ml. Early rejection can be difficult to diagnose, as its recognition usually requires a kidney biopsy, which may be risky in a fresh transplant. Moreover, different types of rejection may need to be distinguished, as they require different therapeutic responses. Especially in presensitized recipients, acute rejection may not only be cellular- but also antibody-mediated, i.e. humoral, necessitating the initiation of plasmapheresis and potentially other specific therapeutic measures instead of treatment for cellular rejection, which consists of steroid pulses or the application of depleting anti-T cell antibody products. Moreover, cellular and humoral rejection can coexist, and the recognition of humoral rejection requires special studies both on the biopsy material, i.e. staining for C4d, and in the blood, i.e. identification of antidonor antibody.[81]

Additional complications resulting in early impairment of graft function are thrombosis of the renal vein or one of its major branches, obstruction of urine flow, e.g. by a blood clot, and urinary leakage, e.g. from an unsatisfactory ureteral anastomosis. Ultrasound and nuclear scan are useful tools to identify these problems.

Surgical/urologic complications of transplantation

A comprehensive review of surgical complications[82] of renal transplantation reveals technical problems in 13% of transplant operations, 35% of which resulted in graft loss. Urologic complications other than uncomplicated UTIs occurred in 5.6% and consisted primarily of urinary extravasation, ureteral anastomotic obstruction, ureteral necrosis, and symptomatic VUR. Urologic complications resulted in allograft loss in 31% of cases.

Renovascular complications were encountered in 5.5% of cases, with a 3.2% incidence of technical vascular problems consisting of renal artery stenosis or thrombosis and renal vein thrombosis. Of note, 86% of all vascular complications and 74% of technical vascular complications resulted in allograft loss. Renal artery and vein thromboses are associated with particularly high incidences of graft loss and may have a technical (e.g. anastomotic defect, vascular angulation, or compression) or a non-technical cause (e.g. a low-flow state, intimal injury from harvesting, cannulation, or existing donor vascular disease). Renovascular stenosis may be managed by percutaneous transluminal angioplasty,[83] although some centers have reported greater success with primary surgical reconstruction.[84]

Wound complications occurred in 4.2% of patients and consisted primarily of lymphocele, hemorrhage, and infection. Hemorrhage was associated with a 44% incidence of graft loss, and allograft rupture was reported in 2.4% of patients, generally associated with rejection. In several instances, hemorrhage was controlled and the kidney surgically salvaged, leaving a 57% incidence of acute graft loss. Long-term follow-up, however, has revealed a very poor prognosis regarding long-term function.[85,86]

Urolithiasis can complicate renal transplantation in approximately 6% of adult[87,88] and 5% of pediatric cases,[89–91] creating a particularly challenging situation because of the increased difficulty experienced with endoscopic stent placement and ureteroscopy in the post-transplant setting. A multifactorial etiology of urolithiasis has been demonstrated with low urine output, elevated calcium excretion, and possibly disturbances in uric acid metabolism secondary to CI therapy. Additional factors include increased frequency of UTIs, alkaline urinary pH, hypocitraturia, hypomagnesuria, hypophosphaturia, and hyperparathyroidism found in 36% of patients. A surgical cause for urolithiasis can also be retained suture material.[89] For stone management, extracorporeal shock wave lithotripsy (ESWL)[92] and/or endourological approaches[93] can be used.

The significance of VUR post-transplant has been the subject of intense discussion. When VUR was

detected by routine post-transplantation screening, no statistical significance in the survival of patients or grafts has been demonstrated for adults[94] or children.[95] However, pathologic data from VUR-associated pyelonephritis in transplanted pediatric kidneys suggests that its occurrence reduces long-term survival of renal allografts.[96] Adult series have shown that no patient had greater than grade III reflux, whereas in the pediatric series all patients with greater than grade III reflux underwent antireflux surgery. More recently, endoscopic management of reflux has been attempted,[97] but this has shown little success. Most often, the underlying problem is occult or incompletely managed bladder dysfunction, and the reflux is controllable by management efforts directed at the bladder, which may require anticholinergics and/or IMC. Dilating reflux in the absence of a dysfunctional bladder should be considered for correction, because such reflux in young recipients is associated with a definite risk of pyelonephritis and subsequent allograft injury.[98] VUR has also been implicated as a significant etiologic factor for hypertension on long-term follow-up.[99]

Transition to outpatient management

After successful kidney transplantation, children typically spend at least a week in the hospital recovering from the procedure. During this time, their fluid, caloric, and medication intake is adjusted to their outpatient regimen, and central lines as well as bladder catheters are removed in most cases.

Transition to outpatient care occurs on an individualized basis, depending on medical as well as geographical aspects. Local patients will continue to be seen frequently at the transplant center, initially several times a week, whereas other patients, who may have been referred for transplantation from a nephrology care provider further away, may return rapidly to care rendered by that provider. Recipients with complex lower urinary tracts will also require long-term urologic follow-up.

Maintenance management, including immunosuppression

After hospital discharge, patient management is largely focused on maintaining graft function without overly toxic or complex treatment regimens, so as to facilitate maximal patient rehabilitation with regards to growth and development, allowing as 'normal' of a childhood as possible with regular school participation and sports or other extracurricular activities. Historically, maintenance of graft function largely consisted of the prevention or at least prompt recognition and treatment of acute rejection. With the application of the latest immunosuppressive strategies, however, the incidence of acute rejection in the first 6–12 post-transplant months should be less than 15%, and the most common reason for rehospitalization of pediatric kidney transplant recipients is now infection and not rejection.[100] These trends, paired with the almost inevitable development of CAN over time[69,74] and the considerable incidence of PTLD,[101] imply that a number of patients (probably excluding those at high immunologic risk) may currently be overimmunosuppressed. Discussions and efforts are therefore under way to develop more appropriate regimens for rejection prophylaxis, taking into consideration an individualized risk profile based on a variety of graft and recipient factors (see above). Generally, prudent combinations of several antirejection agents, adjusted based on various parameters as outlined above, will remain the mainstay of immunosuppressive therapy as long as the advent of protocols capable of inducing true immunologic tolerance remains uncertain. Of note, evidence is beginning to accrue in support of long-term administration of mycophenolate mofetil as antiproliferative immunosuppressant agent of choice as part of such a combination[102] (see Table 24.9).

Long-term aspects

Current survival statistics (see Figure 24.1 and Table 24.6) document excellent short- and mid-term patient and graft survival for children with kidney transplants, comparable with the outcomes of adult kidney transplantation. However, controversy exists regarding long-term outcomes, largely because of the propensity of the current immunosuppressive protocols to contribute to CAN, the leading actual cause of graft failure in adults after the first post-transplant year, and CV disease, the leading cause of death amongst adult kidney transplant recipients.[74,103] Therefore, and although half-lives of over 35 years for renal allografts from living donors have been predicted recently by some clinicians,[104] the challenge for the future is to develop better long-term care regimens for kidney transplant recipients with special emphasis on the problems of CAN and CV disease.[69]

Moreover, such optimistic half-life predictions are not shared by other clinicians,[105] and even a transplant half-life of 30 or 40 years would theoretically appear insufficient for children, as a substantial number of transplants would still be lost rather early during their adulthood. Accordingly, there is already a growing population of patients at especially high immunologic risk: namely, those who have lost a previous kidney transplant or are recipients of another organ transplant and have developed renal failure from chronic CI toxicity or for other reasons. These individuals not only compete with first-time transplant candidates for organs but they also have a high incidence of sensitization from their previous or ongoing alloexposure and are thus more difficult to transplant and to manage post-transplant.[18,19]

Another emerging challenge in the medical management of children with kidney transplants is the provision of a meaningful transition from teenage to adulthood, including transfer of their transplant-related care to providers for adults. In fact, teenage and the transition phase into adulthood are associated with an increased incidence of adverse outcomes, at least in part due to more frequent non-compliance.[16] Better strategies to enhance compliance during these critical stages in the life of pediatric transplant recipients are thus urgently needed.

Lastly, adequate living kidney donor follow-up is required because of the donor's increased risk of hypertension and proteinuria several decades after donation.[55] Along these lines, efforts to standardize this follow-up and to create a donor registry are under way in the United States. Some unfortunate former donors have even lost function of their remaining kidney, either because of trauma, malignancy, or kidney disease that was not apparent at the time they donated, and these individuals are given very high priority in the organ allocation algorithm currently in place via the United Network for Organ Sharing.

Summary

Renal transplantation is the treatment of choice for pediatric patients with ESRD and is associated with excellent short- and mid-term outcomes, at least in recipients without extraordinary immunologic or other risk factors. In many children receiving a kidney allograft, urologic issues are of special importance before, during, and after transplantation because of the comparably high incidence of urologic disease in this age group. Important current challenges revolve around optimal long-term outcome, specifically CAN, chronic CI nephrotoxicity, other complications of prolonged administration of immunosuppressive agents, and compliance.

Renal calculus disease

25

Pramod P Reddy and Eugene Minevich

Introduction

The purpose of this chapter is to review the current knowledge of pediatric urolithiasis, with the emphasis being on the pathophysiology, clinical presentation, evaluation, and medical management of this condition. The surgical management of urinary calculi will be addressed in Chapter 26.

It is well established that pediatric urolithiasis is a distinctly different condition and is not as common as adult urolithiasis; however, there are quite a few similarities in the presentation and evaluation of this condition regardless of the age of the patient. Urolithiasis is an important manifestation of disease conditions, with lifelong implications.

Epidemiology of pediatric urolithiasis

Children account for only 2–3% of all patients with calculous disease.[1,2] Pediatric urolithiasis is endemic to certain developing countries such as Turkey, India, and Thailand, and until recently was a relatively rare condition in the Western Hemisphere. The incidence in the USA has been increasing over the past decade, possibly due to changing dietary and physical activity patterns in our pediatric population. In the USA, urinary stone disease accounts for 1:1000 to 1:7600 hospital admissions, whereas in countries where stone disease is endemic the incidence is approx 1:1000 to 1:3000.[3] There has also been a shift in the pathophysiology of the stones encountered in the USA. Previously the majority of the stones were felt to be secondary to an identifiable underlying metabolic disorder.[4,5] Recent data, however, suggest that pediatric urolithiasis is evolving to a more adult-type pathophysiology, possibly due to changing dietary habits and lack of regular exercise in this age group.

Urinary calculus disease is more common in Caucasians, less commonly affecting those of African or Latin-American heritage.[1] Boys and girls appear to be affected equally, despite earlier data suggesting a male preponderance.

The mean age at presentation is 6.9 years for girls and 5.2 years for boys.[6] Infected stones tend to occur more frequently in children under 4 years of age. In the pediatric population the rate of recurrence of stones ranges from 3.6% to 68% and appears to be the highest for children with underlying metabolic risk factors.[7,8] It is the high recurrence rate that suggests that all children with stones should undergo a metabolic evaluation.

Classification

Several classifications have been proposed to organize pediatric stone disease. The schema proposed by Smith and Segura is one of the most comprehensive and useful systems that we have encountered (Table 25.1).

Pathophysiology of urolithiasis

Formation of a stone in the urinary tract is a consequence of complex physical processes and represents the end manifestation of a multitude of diseases. The stone is produced as the culmination of many interrelated anatomic and physiochemical processes.[10] The major factors are supersaturation of lithogenic ions and crystallization of compounds in the urine. The formation of stones is influenced by urinary volume, pH, and the presence of urinary ions or compounds that function as promoters or inhibitors of lithogenesis.

Table 25.1 Classification of urolithiasis in children

Enzyme disorders
Primary hyperoxaluria (deficiency of hepatic peroxisomal alanine–glyoxylate aminotransferase):
- Type 1: glyoxylic aciduria
- Type 2: glyceric aciduria

Xanthinuria (deficiency of xanthine dehydrogenase):
- 1,8-Dihydroxyadeniuria
- Lesch–Nyhan syndrome (hyperuricosuria due to deficiency of hypoxanthine–guanine phosphoribosyl transferase, HPRT)

Renal tubular syndromes
Cystinuria
Renal tubular acidosis (types 1–4)(calcium phosphate stones)

Hypercalcemic states
Hyperparathyroidism
Immobilization

Uric acid lithiasis

Enteric urolithiasis

Idiopathic calcium oxalate urolithiasis
Solute excess:
- Hypercalciuria:
  Absorptive (Dent disease, Bartter syndrome)
  Renal
- Hyperoxaluria
- Hyperuricosuria
- Hypocitraturia
- Medications excreted into the urine (sulfadiazine, indinavir, etc.)

Endemic bladder stone formation

Secondary urolithiasis

Infection (struvite stones, secondary to UTI with bacteria that produce urease)
Obstruction (UPJ obstruction, UVJ obstruction, neurogenic bladder, exstrophy)
Structural abnormalities
Urinary diversion procedures
Foreign body (ureteral stent, suture, etc.)

UTI, urinary tract infection; UPJ, ureteropelvic junction; UVJ, ureterovesical junction.
Modified from Smith and Segura.[9]

The central event in calculus formation is supersaturation. If a urinary solute exceeds its solubility product (K_{sp} = a constant that is equal to the product of the concentrations of the pure chemical components at which the solid and the dissolved states are in equilibrium in water at standard conditions and temperature), crystallization of the solutes can occur. In normal individuals urine is undersaturated. When a solute is added to a solvent it dissolves in it until an equilibrium point is achieved [supersaturation (SS = 1)]. Beyond this point (i.e. between saturated and supersaturated states – metastable zone) no further dissolution is possible but new nuclei do not form spontaneously.[11]

In normal urine, the concentration of a component necessary to reach supersaturation is several times higher than would be expected from its solubility because of the presence of naturally occurring organic and inorganic inhibitors that raise the K_{sp} of the urinary solutes (i.e. magnesium, citrate, pyrophosphate, glycosaminoglycans, nephrocalcin, and Tamm–Horsfall protein).[12–16] Complexing agents are substances that form soluble complexes with specific crystals. Depending on the specific stone-forming substance, some chemicals such as citrate and magnesium may act as a complexor and/or an inhibitor.

Once urinary solutes exceed their K_{sp}, the solvent is said to be saturated (unstable zone) (Figure 25.1). Crystallization occurs via homogeneous nucleation (on itself) or heterogeneous nucleation (on top of particulate matter; i.e. other crystals, cells, and tubular casts). In vivo, heterogeneous nucleation is much more common. Once this process is initiated, growth of the stone is fostered by the nuclei coming in close contact and binding to each other (due to chemical and/or electrical forces), resulting in crystal aggregation (Figure 25.2).[11] Urinary pH influences the solubility of various lithogenic ions. Uric acid and cystine are more soluble in alkaline urine (pH >7.0).

Crystal retention and formation of calculi takes place initially in the papillary duct. Disorders of metabolism, or endocrine or urologic abnormalities may lead to the development of crystallized material in the urinary tract (Figure 25.3).

Any condition that results in urinary stasis – i.e. ureteropelvic junction (UPJ) obstruction, vesicoureteral reflux (VUR) – promotes growth of a stone by increasing excretion of stone-forming constituents, crystal aggregation and retention, and a decrease in the excretion of inhibitors or complexing agents. It is very important that in reality a combination of factors are involved in the genesis of urinary calculi.

Clinical presentation

The clinical manifestations of pediatric urinary stones are dependent upon a number of factors:

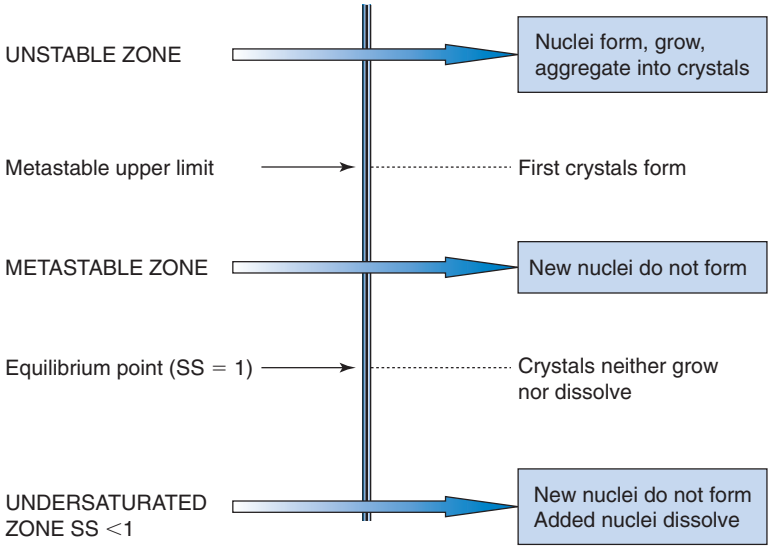

Figure 25.1 Supersaturation (SS) of urine.

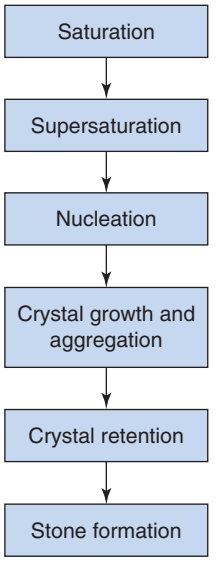

Figure 25.2 Progression of lithogenesis.

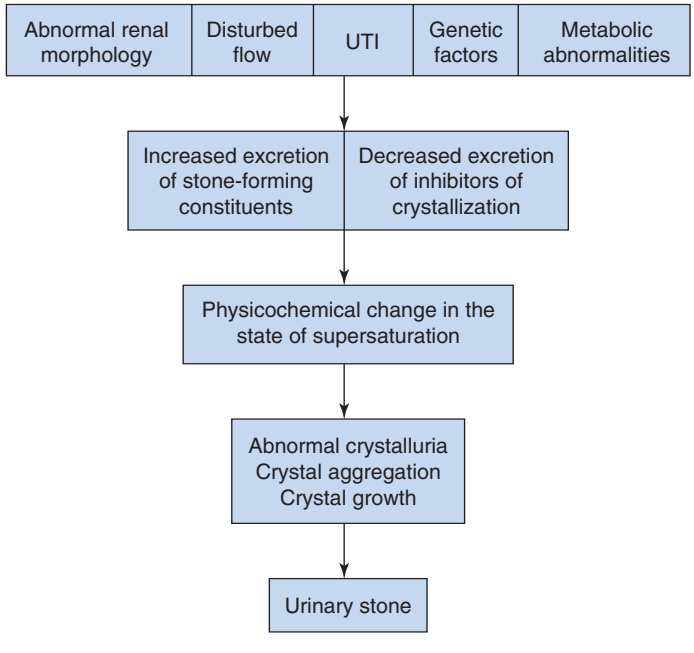

Figure 25.3 General aspects of lithogenesis. UTI, urinary tract infection.

- size of the stone
- location of the stone
- degree of obstruction to the flow of urine
- presence of infection
- presence or absence of a normal contralateral renal unit.

Presentation tends to be age-dependent, with symptoms such as flank pain and hematuria being more common in older children. Non-specific symptoms such as irritability and vomiting are more common in younger children.

Most symptoms related to urolithiasis occur when the calculus becomes lodged in the ureter, causing partial or complete obstruction. Typically, an obstructing calculus causes either renal colic and/or an infection. Renal colic, which occurs in approximately 40–75% of children with urolithiasis,[17,18]

presents with a sudden onset of severe cramp-like flank, abdominal, or pelvic pain associated with gastrointestinal symptoms (nausea and vomiting). Irritative voiding symptoms (i.e. dysuria, urgency, and frequency) occur when the calculus is in the distal one-third of the ureter. In some patients the pain can present as diffuse abdominal pain and can obscure the clinical picture, delaying the correct diagnosis.[19]

Microscopic or macroscopic hematuria has been reported in 33–90% of children with urinary stones.[20]

Urinary tract infection (UTI) may complicate the clinical presentation, especially in an obstructed kidney, and may not be associated with acute renal colic, but rather persistent flank pain. The combination of flank pain and fever should immediately raise the suspicion for the presence of acute pyelonephritis occurring in the setting of an obstructed calculus, and this requires emergent intervention.

Children with urethral stones often present with terminal hematuria or the inability to void.

On physical examination, most children will be restless and costovertebral angle (CVA) tenderness may be elicited on the affected side. This presentation is less specific in younger children or renal transplant patients. Children under 5 years of age frequently present with symptoms suggestive of a UTI. Asymptomatic stones may be identified in children who are undergoing abdominal imaging for non-urologic diagnoses (i.e. acute appendicitis).

Evaluation of patient with urolithiasis

History and physical examination

The initial evaluation of a pediatric patient with urolithiasis may suggest the diagnosis through a complete history and physical examination. The evaluation should begin with a review of the history and include questions regarding:

- prematurity (especially with the use of furosemide), supplemental vitamin D, or enteral/parenteral nutrition formulas high in calcium and/or phosphorus
- current medications (i.e. steroids, chemotherapeutic agents, diuretics, protease inhibitors)
- concurrent illnesses (i.e. cystic fibrosis, neoplasms, seizures)
- recurrent skeletal fractures, which could indicate the presence of hyperparathyroidism or other bone disease
- nutritional habits (i.e. ketogenic diet, dietary excesses or deficiencies, type and amount of fluid intake)
- family history of nephrolithiasis, gout, or bowel disease.

A wide variety of medical conditions can be associated with urolithiasis in children. These include gastrointestinal (GI) disorders, resulting in malabsorption, chronic corticosteroid treatment, cystic fibrosis, myelodysplasia, and immobilization. The family history is helpful in patients with autosomal recessive disorders, such as cystinuria and primary hyperoxaluria, or with autosomal dominant diseases, such as renal tubular acidosis (RTA) or the syndrome of idiopathic calcium oxalate urolithiasis.

The physical examination should screen for chronic disease, including failure to thrive (distal RTA); hypertension as an indicator of underlying renal parenchymal injury; the characteristic bony deformities of rickets; photophobia due to band keratopathy (hypercalcemia-induced metastatic calcification); and evidence of UTI.

Imaging

The radiographic work-up of a child with suspected urolithiasis is relatively straightforward. Imaging modalities such as plain films of the abdomen [kidney, ureter, and bladder (KUB)] can be useful in detecting stones, and also suggesting the type of calculi (Table 25.2). Calcium oxalate stones are usually <2 cm in size, whereas struvite, uric acid, or cystine stones may fill the entire collecting system, i.e. staghorn calculi.

Renal and bladder ultrasound (US) and intravenous urography (IVP) are also useful in the diagnosis of urolithiasis and evaluating the degree of obstruction caused by the stone. The use of IVP is limited in the pediatric population because of concerns about the risks of cumulative radiation exposure. Currently, in both adult and pediatric stone

Table 25.2 Radiodensity of calculi on plain film imaging

Radiopaque calculi	Radiolucent calculi
Calcium oxalate	Uric acid
Calcium phosphate	2,8-Dihydroxyadenine

	Xanthine
Cystine	Silica

patients, the unenhanced, helical computeted tomography (CT scan) is the gold standard technique for radiologic evaluation of acute flank or abdominal pain. It allows for an accurate and timely diagnosis of obstructed urinary calculi and can also detect extraurinary lesions.[21,22] CT scanners are readily available in most pediatric institutions and have the advantages of the brevity of the scan and avoidance of intravenous contrast (and any associated adverse reactions), although concerns about radiation exposure also exist.

Voiding cystourethrogram (VCUG) and renal nuclear scintigraphy may be necessary to rule out associated anatomic abnormalities in some patients. Children with suspected neurogenic bladder and significant voiding dysfunction may benefit from urodynamic studies, to complete their evaluation when dealing with chronic or recurrent urolithiasis.

Laboratory evaluation

The evaluation of the patient may be divided into two phases – evaluation during an acute stone episode to direct therapy and subsequent evaluation to determine the underlying etiology of the stone. Owing to the high incidence of predisposing factors for urolithiasis in children (up to 75%) as well as the frequency of stone recurrences (up to 65%),[17] a complete evaluation of every child after the very first urinary stone is advisable.[23,24]

During the acute phase, the following tests are recommended:

1 Urine for urinalysis (UA) and culture and sensitivity (C&S). UA usually demonstrates hematuria, whereas pyuria may be a first sign of a UTI, which is confirmed with a urine culture.
2 Serum electrolytes, blood urea nitrogen (BUN), and creatinine. Determination of serum creatinine is helpful in grossly evaluating the renal function.
3 Complete blood count (CBC).
4 Serum for Ca^{2+}, phosphorus, magnesium, and parathyroid hormone (PTH) levels may be useful in determining the type of stone being treated.

After treating the acute stone episode, it is of critical importance to collect a 24-hour urine sample in order to determine a stone-risk profile and to rule out any subtle metabolic abnormalities. The urine collection is evaluated for volume, pH, calcium, uric acid, creatinine, sodium, oxalate, citrate, and cystine.

Supersaturation indices are felt to accurately predict stone composition and may be a more precise predictor of response to therapy.[25,26] We prefer two consecutive 24-hour urine samples as initial evaluation, ideally after the patient is free of stones. During the collection of 24-hour urine samples, patients should maintain their usual diet and fluid intake. We use urinary supersaturation values as the principal laboratory benchmark index of possible crystal formation. Adult reference ranges for urinary supersaturation indices do not accurately reflect the pathophysiology in children.[27] In a recently published study we have shown that there are significant differences in the normal ranges of urine chemistries of children and adults. Calcium, oxalate, and citrate levels are significantly higher in children than adults when referenced by creatinine (Table 25.3).[28] Chemical analysis and determination of the composition of the stone (with polarization microscopy, infrared imaging, or X-ray diffraction) should be performed whenever possible. The patient should be given a urine strainer to retrieve any stones that are passed in the urine.

In this next section we will discuss the pathophysiology and specific treatment of the various types of stones encountered in children.

Approximately 75% of all pediatric kidney stones in the USA are composed of calcium oxalate; these stones are usually mixed calculi with some component

Table 25.3 Mean pediatric and adult urine chemistry values

Parameter	Pediatric	Adult	*P*-value
Urine pH	6.44 ± 0.40	6.05 ± 0.41	<0.001
SS Uric acid	0.59 ± 0.53	1.14 ± 0.99	<0.001
SS Ca oxalate	7.88 ± 4.13	7.85 ± 6.30	1.00
SS Ca phosphate	2.48 ± 1.31	1.42 ± 1.19	<0.001
Citrate/Cr (mg/g)	592 ± 460	373 ± 216	0.01
Oxalate/Cr (mg/g)	41.2 ± 26.7	23.1 ± 15.0	<0.001
Ca/Cr (mg/g)	172 ± 99	113 ± 55	0.001
Uric acid/Cr (mg/g)	623 ± 390	396 ± 89	0.01

SS, supersaturation; Ca, calcium; Cr, creatinine.

of hydroxyapatite, or uric acid. The 10–20% of stones composed of struvite (magnesium ammonium phosphate) are usually encountered in the clinical setting of recurrent UTI;[29] 5% of stones are uric acid and 5% are composed mainly of brushite (calcium monohydrogen phosphate), whereas <1% are composed of cystine.[30]

Idiopathic calcium oxalate urolithiasis

Hypercalciuria

Hypercalciuria is the most common predisposing metabolic factor for stone formation in children. In general, children with a history of calcium oxalate urolithiasis excrete a higher fraction of dietary calcium in their urine than unaffected children.[17] Normal calcium excretion in children is <4 mg/kg/day. Hypercalciuria occurs in 53–81% of children with calcium stones.[31,32] Microscopic or gross hematuria may be encountered in children with hypercalciuria without urolithiasis, although up to 20% of them will develop stones within 5 years.[33,34] Hypercalciuria has also been reported in association with the urinary frequency-dysuria syndrome.[35] Hypercalciuria is seen with a higher prevalence than in the normal population in children with Beckwith–Wiedemann syndrome and cystic fibrosis.[36] Initial studies of idiopathic hypercalciuria suggested two relatively easily defined and genetically distinct subtypes of hypercalciuria, 'renal' and 'absorptive'.[37] Recent reports have postulated that absorptive and renal forms of hypercalciuria appear to represent a continuum of a single disease process.[38]

Absorptive hypercalciuria, by far the most common cause of excessive urinary calcium, results from an increased intestinal absorption of calcium, which is caused by either overly aggressive vitamin D supplementation or excessive ingestion of calcium-containing foods (milk-alkali syndrome). Increased intestinal calcium absorption produces a corresponding increase in serum calcium levels. Typically, serum PTH is in the low-normal range in absorptive hypercalciuria because of feedback from the high serum calcium level. Fasting urinary calcium levels are usually within the normal range in these patients.

Three types of absorptive hypercalciuria have been defined. In Type I, patients have hypercalciuria without calcium load, which is relatively uncommon and is the most severe type of absorptive hypercalciuria. In Type II, the most common variety, patients have hypercalciuria only, with a high calcium intake. In Type III, a relatively rare cause of hypercalciuria, the underlying etiology is a renal defect that causes excessive urinary phosphate excretion. This is suspected to result from inactivation of the renal epithelial sodium–phosphate cotransporter – NaPi2. The continuous urinary phosphate loss rapidly depletes the serum phosphate level, causing hypophosphatemia. This results in activation of vitamin D_3, which increases intestinal absorption of both phosphate and calcium. The absorbed calcium is ultimately excreted in the urine, causing the hypercalciuria.

Renal hypercalciuria results from a specific defect in the kidneys that allows excessive obligatory urinary calcium excretion, regardless of serum calcium levels, body stores, or calcium ingestion. The calcium:creatinine ratio is usually high (>0.20). The loss of serum calcium into the urine produces a mild hypocalcemia and secondary hyperparathyroidism, which is useful in diagnosing this condition. Renal leak hypercalciuria is far less common than absorptive hypercalciuria.

Hyperoxaluria

This condition is discussed in depth in a later section. Up to 20% of patients with idiopathic calcium oxalate urolithiasis will have hyperoxaluria.[17] Oxalate has a very strong chemical affinity for calcium, and calcium oxalate has a relatively low solubility. This is most frequently due to idiopathic hyperoxaluria, in which case urine oxalate values are only mildly elevated. It may be due to simple dietary excess of high-oxalate food sources or to an increased endogenous oxalate production. In patients with enteric hyperoxaluria, calcium stones develop because of fat malabsorption, which in turn results in colonic hyperabsorption of ingested oxalate. The latter occurs because malabsorbed fatty acids bind luminal calcium, which is then unavailable to precipitate and prevent the uptake of ingested oxalate.[39] Enteric hyperoxaluria is seen in patients with intestinal malabsorption or inflammatory bowel disease and may be treated with dietary adjustment and citrate supplementation.

Hyperuricosuria

Hyperuricosuria commonly occurs in patients with idiopathic calcium oxalate urolithiasis.[40,41] Hyperuricosuria may be the result of a diet high in purines, uricosuric drugs, or from tubular defects such as an isolated defect in renal tubular urate reabsorption, or from generalized tubular dysfunction. It can also occur in patients undergoing chemotherapy with rapid cell turnover, and in those who are in a negative

nitrogen balance (catabolic state). Hyperuricosuria leads to calcium oxalate crystallization by heterogeneous nucleation and by reducing the levels of urinary inhibitors.[42,43]

Hypocitruria

Hypocitraturia is a risk factor for urinary stone formation in patients with idiopathic calcium oxalate urolithiasis.[44] Urinary citrate has a direct inhibitory effect on the crystallization and precipitation of calcium salts. It binds to calcium ions in the urine, reducing calcium ion activity, which results in a lowering of the supersaturation of calcium phosphate and calcium oxalate. It also increases the inhibitory activity of other urine macromolecules (e.g. Tamm–Horsfall protein) and may reduce the expression of urinary osteopontin, which is an important component of the protein matrix of urinary stones. In addition, urinary citrate excretion can increase urinary pH, which negatively influences uric acid crystallization and uric acid stone formation. Citrate excretion is impaired by acidosis, hypokalemia (causing intracellular acidosis), a high animal protein diet (with an elevated acid-ash content), and UTI. Acidosis reduces urinary citrate both by enhancing renal tubular reabsorption and reducing the synthesis of citrate. RTA is the most common cause of hypocitriuria in children.

Medical management

Since the single greatest risk factor of pediatric urinary stones is a low urinary flow rate,[45] the management of all patients with metabolic stones starts with maintaining an adequate level of oral fluid intake, even in young children. One should strive to maintain urine output greater than 2 L/day for adolescents and approximately 35 ml/kg/day for children.[46,47] Carbonated beverages are to be avoided and do not count as an appropriate oral fluid in these patients.

Calcium restriction in the growing infant, child, or adolescent should be avoided, as it only increases the risk for poorly mineralized bones. There appears to be widespread agreement that restriction of calcium intake contributes to the severity of a patient's osteopenia.[48,49] Individuals having elevated urine sodium:potassium ratios seem most responsive to the hypocalciuric effects of increased potassium intake in combination with a low-salt diet.[50] Dietary manipulations should initially be directed towards dietary excesses or deficiencies, and placing the child on a balanced and nutritious diet. The most frequently used medications to correct hypercalciuria are thiazide diuretics (1 mg/kg/day), which act to lower urinary calcium excretion by increasing the fractional calcium absorption by the distal nephron.[51] If RTA is suspected, potassium or sodium citrate is indicated, as it corrects the systemic acidosis, hypercalciuria, hypocitraturia, and hypocalcemia.[52] Children with type 3 absorptive hypercalciuria (phosphate leak) may benefit from treatment with orthophosphates.[3] Patients with urolithiasis secondary to a ketogenic diet need to be managed in close consultation with their neurologist, as these patients are on a very strictly regimented diet, in terms of volume and caloric intake (Table 25.4).

Hypercalcemic states

Hyperparathyroidism

Resorptive hypercalciuria results from the loss of calcium from the body's normal stores in the bony

Table 25.4 Dietary recommendations for pediatric patients with calcium urolithiasis

Nutrient	Dietary recommendation
Fluid intake	Maintain urine output >2 L/day for adolescents and >20 ml/kg/day for younger children
Dietary sodium	No added salt diet (maintain Na <2 g/day)
Dietary calcium	Recommended daily allowance of calcium for age; avoid calcium restriction in children
Dietary protein	Recommended daily allowance; avoid excessive animal protein intake
Dietary potassium	Five servings per day of high-potassium, low-oxalate foods
Dietary phosphorus	Recommended daily allowance
Dietary magnesium	Recommended daily allowance

skeleton and is typically diagnosed in children with hyperparathyroidism. Although primary hyperparathyroidism is not a common cause of hypercalcemic hypercalciuria in children, it must be considered in a patient with elevated serum calcium.[18] In this condition, calcium is released from bone in response to the increased activity of osteoclasts caused by excessive and inappropriate serum PTH levels. This causes significant hypercalcemia. Under normal conditions, PTH causes the kidney to limit calcium excretion, but, with the overwhelming serum calcium load produced with hyperparathyroidism, the kidneys are forced to excrete the extra calcium into the urine, resulting in hypercalciuria.

Immobilization

Immobilization of children is the most common cause in North America of secondary hypercalciuria.[6] The patients primarily at risk are those acutely immobilized for the management of fractures or postoperative management, as opposed to those with static neurologic disorders who are chronically bedridden (i.e. spastic quadriplegia).

Others

Gastrointestinal hyperabsorption can be secondary to symptomatic vitamin D intoxication characterized by failure to thrive, anorexia, polyuria, and dehydration, and variable degrees of renal insufficiency. The hypercalcemia of sarcoidosis is due to excessive 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) production by alveolar macrophages and in sarcoid granulomas. In the management of these conditions associated with hypercalcemia, it is critical to identify the underlying cause and correct it.

Uric acid lithiasis

Uric acid calculi are radiolucent and constitute up to 5% of the urinary calculi encountered in pediatric patients. These stones are usually white or orange. Uric acid crystals are orange and can often be mistaken for blood by the patient or their parents. A pH <5.8 promotes uric acid crystal precipitation, since they are poorly soluble in acidic urine. In the familial, or idiopathic, form of the disease, affected children have hyperuricosuria and normal uric acid serum concentration. Generalized dysfunction of tubular reabsorption, as seen in patients with Wilson's disease or various forms of the Fanconi syndrome, is associated with familial hyperuricosuria.

Disorders associated with overproduction of uric acid include inborn errors of metabolism such as Lesch–Nyhan syndrome and type I glycogen storage disease (glucose-6-phosphatase deficiency).[54] Uric acid overproduction can also occur secondary to myeloproliferative disorders (presenting acutely or in relapse), or other causes of cell breakdown (catabolic states induced by neoplasms or chemotherapy). Hyperuricosuria may be the result of a high purine intake or uricosuric drugs (such as probenecid, salicylate) or from tubular defects such as an isolated defect in renal tubular urate reabsorption, or from generalized tubular dysfunction.[55] Chronic diarrheal syndromes (e.g. ulcerative colitis, regional enteritis) or jejunoileal bypass surgery may cause uric acid lithiasis by inducing net alkali deficit and lowering urine volume (thereby reducing urinary pH and augmenting urinary concentration of uric acid, respectively).[56] The majority of patients with hyperuricosuria have coexistent hypercalciuria; therefore, calcium oxalate urolithiasis may be seen in these children as well.[40]

Since most of these patients have a low volume of chronically acidic urine throughout the day, increasing oral fluid intake and urinary alkalinization to a pH of 6.5–7.0 with potassium citrate or sodium bicarbonate are the primary goals of treatment. However, alkalinization of the urine above pH 7.0 can promote calcium phosphate stone formation. Patients with hyperuricemia secondary to myeloproliferative disorders may benefit from decreasing uric acid production with the xanthine oxidase inhibitor allopurinol. A rare complication of prolonged allopurinol therapy is the formation of xanthine stones.[57]

Renal tubular syndromes

Renal tubular acidosis

Renal tubular acidosis is a term applied to several clinical syndromes of metabolic acidosis that result from specific defects in renal tubular hydrogen ion secretion and urinary acidification. Three major types are currently recognized and are differentiated based on the nature of the tubular defect. Stones are composed principally of calcium phosphate (brushite), although calcium oxalate and struvite stones may be seen alone or in combinations.

In type 1 (distal) RTA, the primary functional abnormality is the inability of the distal nephron to establish and maintain a hydrogen ion gradient

between the tubular fluid and the blood. As a result, the urine remains inappropriately alkaline regardless of the severity of the systemic acidemia. Type 1 RTA is associated with renal stone disease in up to 70% of cases. Factors contributing to stone formation include increased urinary pH, hypercalciuria, and hypocitraturia.[58,59] Obstructive uropathy is an example of an etiology of distal RTA.

In type 2 (proximal) RTA, the primary defect is a failure of bicarbonate reabsorption in the proximal tubule, leading to bicarbonate wasting. However, the kidney is able to acidify the urine appropriately and to excrete the daily load of acid, as distal tubular function is spared. Nephrolithiasis and nephrocalcinosis are not seen in proximal RTA.[58]

In type 4 RTA, chronic renal parenchymal damage, leading to moderate reductions in glomerular filtration rate (GFR), produces hyperkalemic, hyperchloremic metabolic acidosis in conjunction with bicarbonaturia, decreased ammonium excretion, and subnormal net acid excretion.[58] Nephrolithiasis and nephrocalcinosis are absent in type 4 RTA.

Type 1 RTA may present as an isolated entity or it may be the secondary manifestation of a variety of systemic and renal disorders, including Sjögren's syndrome, Wilson's disease, primary biliary cirrhosis, and in patients who have undergone a jejunoileal bypass. Children usually present early with familial (autosomal dominant) type 1 RTA. Infants generally present with vomiting and/or diarrhea (>33%) and failure to thrive (>50%), with subsequent growth retardation. Less than 10% have nephrolithiasis and nephrocalcinosis. Children present with metabolic bone disease (osteomalacia) or with signs and symptoms related to stone disease.

Patients with type 1 RTA will present with a hypokalemic, hyperchloremic metabolic acidosis. In these patients, the urinary pH will never fall below 5.5, no matter how low the serum bicarbonate level.[58] Hypocitraturia and hypercalciuria will only be found in type 1 RTA, but are not specific for this disorder. A diagnostic work-up for the presence of incomplete distal RTA is indicated when nephrocalcinosis or recurrent nephrolithiasis of unclear etiology occurs in the absence of spontaneous, non-anion gap acidosis. Although these patients do not have spontaneous metabolic acidosis, they are unable to acidify the urine appropriately when presented with an acid load.[60] This condition is diagnosed by means of an ammonium chloride loading test and monitoring the urine pH. If at any time the urinary pH falls below 5.5, the diagnosis of RTA can be excluded.

Cystinuria

Cystinuria is a complex autosomal recessive disorder, characterized by an abnormality in a specific transport system located in the brush-border membrane of the proximal straight renal tubule and the small intestine. The transporter (SLC3A1 dibasic amino acid transporter) is encoded on chromosome 2p21. Cystinuria results from an excessive urinary excretion of cystine (the disulfide dimer of cysteine) and the dibasic amino acids arginine, lysine, and ornithine.[61,62] Cystine has poor solubility in the normal urinary pH range and a pH below 7 causes cystine to precipitate. Cystine stones are usually very hard and resistant to fragmentation by extracorporeal shock wave lithotripsy (ESWL).

There are three subtypes of cystinuria, and it occurs with a frequency of 1 in 15 000 live births[63,64] and accounts for 1–3% of children with metabolic urolithiasis in industrialized countries.[6] Cystine crystals are characteristically flat, hexagonal, and colorless. Cystine crystals are diagnostic, but are detected in only 19–26% of homozygous cystinuric patients.[62] Cystinuria has been associated with hyperuricemia, uric acid urolithiasis, hemophilia, retinitis pigmentosa, muscular dystrophy, muscular hypotonia, mental retardation, trisomy 21, and hereditary pancreatitis.

The treatment goals of this condition include maintaining a high fluid intake to reduce cystine saturation (the goal is <300 mg cystine/L of urine) with urinary flow rates of up to 50 ml/kg/24 h.[65,66] Further reduction of cystine concentration can be achieved with a diet low in protein and sodium. Urinary alkalinization with potassium citrate at a pH of approximately 7.6 should be maintained in all patients. In children in whom hydration and alkalinization have failed, D-penicillamine (20–50 mg/kg/day) and/or *N*-(2-mercaptopropionyl)glycine (tiopronin; Thiola) (15 mg/kg/day) can be effective in decreasing the rate of stone formation. These drugs can be associated with serious side effects, and patients taking them must be monitored very closely for bone marrow suppression, nephrotic syndrome, and complications resembling systemic lupus erythematosus (SLE) and Goodpasture's syndrome. Thiola has been reported to be better tolerated by pediatric patients. Vitamin B_6 supplementation must be added to patients being treated with either medication. Captopril has also been shown to be effective in lowering the urinary cystine level in homozygous cystinuric patients, by forming a thiol–cysteine mixed disulfide compound that is more soluble in urine than cystine.[67] Patients with cystinuria are at a very high risk for recurrent urolithiasis.[68,69]

Enzymatic disorders

Primary hyperoxaluria

Primary hyperoxaluria is a very rare but serious disorder caused by a congenital defect resulting in very high levels (>200 mg/day) of endogenous oxalate production. Without treatment, the prognosis for these patients is poor. Renal failure occurs in 50% of patients by age 15 years and in 80% by age 30 years. Standard dialysis for uremia cannot remove enough serum oxalate to protect the kidneys and other organs from widespread calcium oxalate deposition (i.e. oxalosis) and calcium oxalate stone production.

Type I primary hyperoxaluria is the more common variety. It occurs in 1 in 120 000 live births and is transmitted as an autosomal recessive trait. It is caused by a deficiency of the peroxisomal liver-specific alanine–glyoxylate aminotransferase enzyme (i.e. AGT). Pyridoxine (vitamin B_6) is a cofactor in this chemical pathway, which normally converts glyoxylic acid ($C_2H_2O_3$) to glycine. Blocking of this pathway because of a deficiency or absence of AGT results in high levels of glycolic and oxalic acid, which are readily converted to oxalate, which is then excreted in the urine.

The median age for presentation of initial symptoms related to hyperoxaluria is 5 years. Oxalate deposition can occur in other organs (e.g. bones, joints, eyes, heart). In particular, bone tends to be the major repository of excess oxalate in patients with primary hyperoxaluria. Bone oxalate levels are negligible in healthy subjects. Oxalate deposition in the skeleton tends to increase bone resorption and decrease osteoblast activity. Because symptoms occur relatively late and are associated with very serious complications, screening all pediatric patients who have stones for hyperoxaluria is important. Discovering this condition may allow earlier testing, detection, diagnosis, and pre-emptive therapy in affected siblings.

Type II primary hyperoxaluria is much less common than type I primary hyperoxaluria and is caused by a deficiency of D-glycerate dehydrogenase (DGDH). This deficiency promotes the conversion of glyoxylate to oxalate. The degree of hyperoxaluria is approximately the same between the two types of primary hyperoxaluria. End-stage renal disease (ESRD) is slightly less common in patients with type II primary hyperoxaluria than in those with type I primary hyperoxaluria.

Primary hyperoxaluria requires vigorous management and careful follow-up. Therapy includes promoting a high urinary flow rate around the clock, and restricting dietary oxalate. Restriction of dietary calcium can result in increased oxalate absorption via the gastrointestinal tract and should be avoided.[20] Pyridoxine supplements (25–250 mg/day) have been shown to lower oxalate production and decrease the need for renal–liver transplantation.[70] Pyridoxine is generally not effective in patients with type II primary hyperoxaluria.

Curative treatment involves a combined kidney and liver transplantation. Renal transplantation alone is insufficient because the liver defect causing the hyperoxaluria is not corrected. In selected patients, an early liver transplantation prior to the development of overt renal failure may preserve the native kidneys, thus avoiding the need for renal transplantation.

Xanthinuria

Xanthinuria is a descriptive term for excessive urinary excretion of the purine base xanthine. The two inherited forms of xanthinuria result from a deficiency of the enzyme xanthine dehydrogenase, which is responsible for degrading hypoxanthine and xanthine to uric acid. The resultant increase in plasma levels and excess urinary excretion of the highly insoluble xanthine leads to urolithiasis, arthropathy, myopathy, crystal nephropathy, or renal failure.[71] More than 50% of the xanthine uroliths occur in children <10 years. Iatrogenic xanthinuria can occur during allopurinol therapy, which is used to reduce urine uric acid excretion in conditions with endogenous overproduction of uric acid. Inhibition of xanthine dehydrogenase by allopurinol may lead to accumulation and urinary excretion of xanthine. No specific therapies are available for classic xanthinuria

Lesch–Nyhan syndrome (hyperuricosuria)

The enzymatic defect associated with Lesch–Nyhan syndrome is a deficiency of the enzyme hypoxanthine–guanine phosphoribosyl transferase (HPRT). This enzyme normally plays a key role in the recycling of the purine bases hypoxanthine and guanine into the purine nucleotide pools. In the absence of HPRT, these purine bases are degraded and excreted, ultimately as uric acid. In addition to the failure of purine recycling, the rate of synthesis of purines is markedly increased, presumably to compensate for purines lost by the failure of the salvage process.

Lesch–Nyhan syndrome is a genetic disorder associated with overproduction of uric acid, neurologic disability, and behavioral problems. The overproduction of uric acid is associated with hyperuricemia. If

left untreated, it can produce nephrolithiasis with renal failure, gouty arthritis, and solid subcutaneous deposits known as tophi. The neurologic disability encompasses a spectrum of extrapyramidal signs, including dystonia, choreoathetosis, and occasionally ballismus. The behavioral problems include cognitive dysfunction, aggressive and impulsive behaviors, and self-mutilation.[72]

The majority of patients present between 3 and 12 months of age with delayed motor development, most commonly hypotonia or failure to reach normal motor milestones. A smaller number of patients present with complications related to the overproduction of uric acid. Sometimes the parents give a history of 'orange sand' in the diapers, which is caused by uric acid crystalluria and microhematuria. Other patients may present with renal failure or frank hematuria, resulting from nephrolithiasis.

The control of uric acid requires allopurinol, which inhibits the metabolism of hypoxanthine and xanthine to uric acid by the enzyme xanthine oxidase.

Generous hydration is essential at all times. Hydration should be increased during periods of increased fluid loss, such as a febrile illness or recurrent emesis.

Infection stones

Infection-related stones constitute about 2–3% of the stones in pediatric patients and most commonly are seen in younger children (<6 years of age). Infection by urea-splitting bacteria results in increased urinary pH (large amount of NH_4) and increased urinary magnesium ammonium phosphate, conditions favoring the formation of struvite stones. Urinary pH of ≥6.8 results from the action of the bacterial enzyme urease on urinary urea. The resultant stones (which have a tendency to grow rapidly and form staghorn calculi) are intrinsically contaminated by bacteria, and the affected children all have findings of persistent pyuria, bacteriuria, and struvite crystalluria. Over 45 types of microorganisms are capable of urease production. *Proteus* spp are isolated in over 70% of all patients with infected stones, although *Pseudomonas, Klebsiella, Streptococcus* and *Mycoplasma* spp may also produce urease.[73]

To treat struvite stones successfully, the stone harboring the infection should be eliminated completely. In such cases, antibiotics alone cannot reach microorganisms and urinary infection recurs as soon as antibiotics are withdrawn. Select patients will benefit from hemiacidrin irrigation, which can dissolve some struvite stones. Acetohydroxamic acid (AHA), a urease inhibitor, is available for the management of stones caused by infection.[74] Genitourinary tract abnormalities predispose to the formation of infected stones (most frequently by obstruction); therefore, careful urologic evaluation of the patient with infected stones is mandatory. Findings of obstruction or a structurally anomalous urinary tract in these patients do not obviate the need for careful metabolic assessment. In one study of 66 patients with structural anomalies of the urinary tract, 36% had coexistent metabolic abnormalities. In the same study, of the 41 patients with infection-related stones, 56% had genitourinary anomalies and 29% had metabolic abnormalities.[17]

Miscellaneous stones

Triamterene stones

Triamterene is a potassium-sparing diuretic: 70% of the orally administered medication appears in the urine; 1 in 1500 patients on this medication will develop stones.[75]

Sulfadiazine stones

Sulfadiazine is a medication that is used to treat toxoplasmosis in patients with human immunodeficiency virus (HIV). Sulfadiazine crystalluria occurs in up to 49% of the patients treated with this medication, but the exact incidence of sulfadiazine causing stones is unknown. Most sulfadiazine stones are radiolucent. Treatment includes hyperhydration and alkalinization of the urine.[76]

Indinavir (Crixivan) stones

Indinavir is a protease inhibitor that is used as an antiviral drug in the treatment of HIV: 20% of the administered medication is excreted unchanged in the urine. Patients who do not maintain a urine output of >1.5 L/day while on this medication will often have crystalluria and occasionally develop indinavir stones.[77] Stone development occurs at higher urine pH (>6.0). These stones are typically radiolucent, and composed of a soft yellowish-brown gelatinous material. Unenhanced computed tomography (CT) imaging may fail to demonstrate these stones, and a high degree of suspicion should be maintained in patients at risk for these stones.[78] ESWL is often not useful in treating these stones, because of their soft nature, but they do respond to hyperhydration and mechanical removal of the stone (i.e. stone basketing).[79]

Summary

Urolithiasis in the pediatric population has diverse etiologies and presentations. With a careful and systematic evaluation of the patient and individualized management strategies, recurrent stones, renal injury, and patient morbidity can be minimized. Once again we would like to emphasize that the adult urinary values for the metabolic stone-risk profile are not accurate for their use in pediatric patients.

Endourology for stone disease

26

Aseem Shukla and Michael Erhard

Etiology/epidemiology

The incidence and prevalence of childhood urolithiasis varies widely throughout the world. In Turkey and Southeast Asia, urolithiasis remains an endemic disease, with an estimated incidence in Turkish schoolchildren of 0.8%.[1] Bladder stones composed of ammonium urate and uric acid indicate dietary etiologies for the disproportionate incidence of urolithiasis in endemic areas. In contrast, pediatric renal stones are rare in North America, with nephrolithiasis accounting for 1 in 1000 to 1 in 7600 pediatric hospital admissions, depending on the geographical region.[2] The incidence of stone disease in children is only one-tenth of that in adults.[3,4] The southeast United States predominates in prevalence.

Only 50% of pediatric patients diagnosed with urolithiasis complain of flank pain.[2] Other presentations include gross or microscopic hematuria (25–40%), incidental finding on imaging examinations (15%), and urinary tract infection (10–30%).[2–5] Stones in infants are often discovered when investigating persistent symptoms of colic.

Spontaneous passage of pediatric urinary stones is common, and conservative management is preferred in the absence of obstructive uropathy, urosepsis, or uncontrolled pain and vomiting. The rate of spontaneous passage will vary according to both the size of the stone and its position within the ureter (Figure 26.1) Adult studies show an overall spontaneous passage of approximately 55% for all stones, with those <4 mm passing approximately 80% of the time.[6] The spontaneous passage rate in children is similarly high, at or near 66% among all pediatric age groups.[7] Other studies have shown that stones within the proximal collecting system pass approximately 22% of the time compared with 46% and 71% for those in the middle and distal third of the ureter, respectively.[8] Previous reports in the pediatric literature concluded that calculi <3 mm have a greater chance of passing spontaneously, whereas stones >4 mm most likely require surgical management.[9] It has been the authors' experience that even small stones that become symptomatic in the proximal ureter are often not likely to advance spontaneously. Furosemide administration in premature infants with bronchopulmonary disease, and the calcium and phosphorus content of premature infant formulas have resulted in a higher incidence of renal stones as compared with ureteral stones in that patient population.[10] In addition, these renal stones are often large and less likely to pass spontaneously. Whereas renal stones in infants are related to specialized medical therapy and systemic illness, urinary metabolic abnormalities commonly contribute to urolithiasis in older children.

If the clinical symptomatology suggests the presence of a urinary calculus, an algorithm similar to that

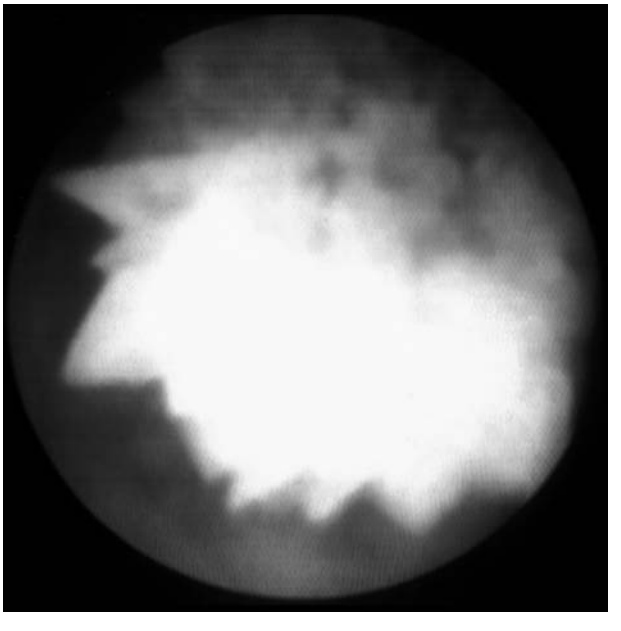

Figure 26.1 Even large stones with a smooth edge and a tapered leading edge may pass through the pediatric ureter; therefore, conservative management should be the first step unless symptoms warrant urgent intervention. Sharp 'spines' when present (as pictured here) may inhibit even a small stone from passing.

in adults, radiographic evaluation with a non-enhanced helical computed tomography (CT) scan of the abdomen and pelvis is most appropriate.[11,12] This will allow complete visualization of the collecting system and should identify all sizes and types of urinary calculi (Figure 26.2). If deemed necessary, intravenous contrast media may be administered after the non-contrast phase to evaluate for obstruction and focal changes in the kidney, providing more information than a traditional intravenous pyelogram (IVP). Most pediatric stones consist of calcium oxalate and may be radiopaque on plain X-ray. Although ultrasound is usually still performed to exclude large renal calculi, hydronephrosis, or perirenal collections, it has very low sensitivity for detecting ureteral calculi.[13] Total radiation exposure in children is a serious consideration, and CT protocols that image stones while reducing dosage are currently under evaluation.[12,14]

Metabolic and genitourinary anomalies that may predispose to urolithiasis often coexist in pediatric patients (Figure 26.3). Anatomic abnormalities, with ureteropelvic junction obstruction being the most common, are discovered in 10–40% of children evaluated for stones.[15] Metabolic abnormalities are exceedingly common and may exist in up to 90% of children with urinary stones, depending upon how strictly they are defined.[7,16,17] Common urine abnormalities include hypercalciuria, hypocitraturia, and hypomagnesuria. Urinary supersaturation indices are often elevated and may prove to be a more precise predictor of stone recurrence than traditional metabolic parameters.[18,19] Low urinary volume is also common and treatment should result in urine output of approximately 35 ml/kg/day.[20] Significant hypercalciuria and hypocitriuria should be aggressively treated in children with recurrent stone disease or multiple or bilateral calculi. Serum electrolyte evaluation is appropriate in children found to have significant urine metabolic abnormalities.

Conservative management is most appropriate for stones of relatively small size (<4 mm) without signs

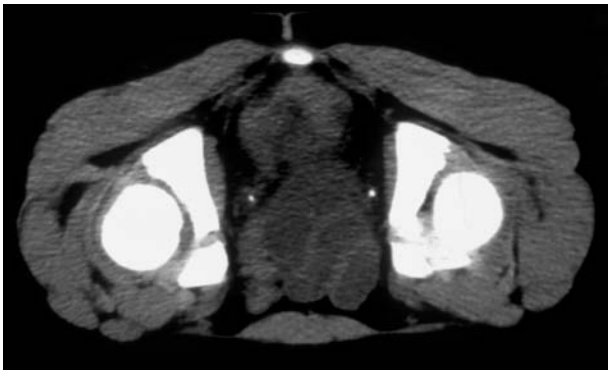

Figure 26.2 CT scan of the abdomen and pelvis allows for complete visualization and diagnosis of even small urinary calculi. This young boy had right-sided symptoms. On radiographic evaluation, he was found to have bilateral ureteral calculi and required subsequent bilateral therapy.

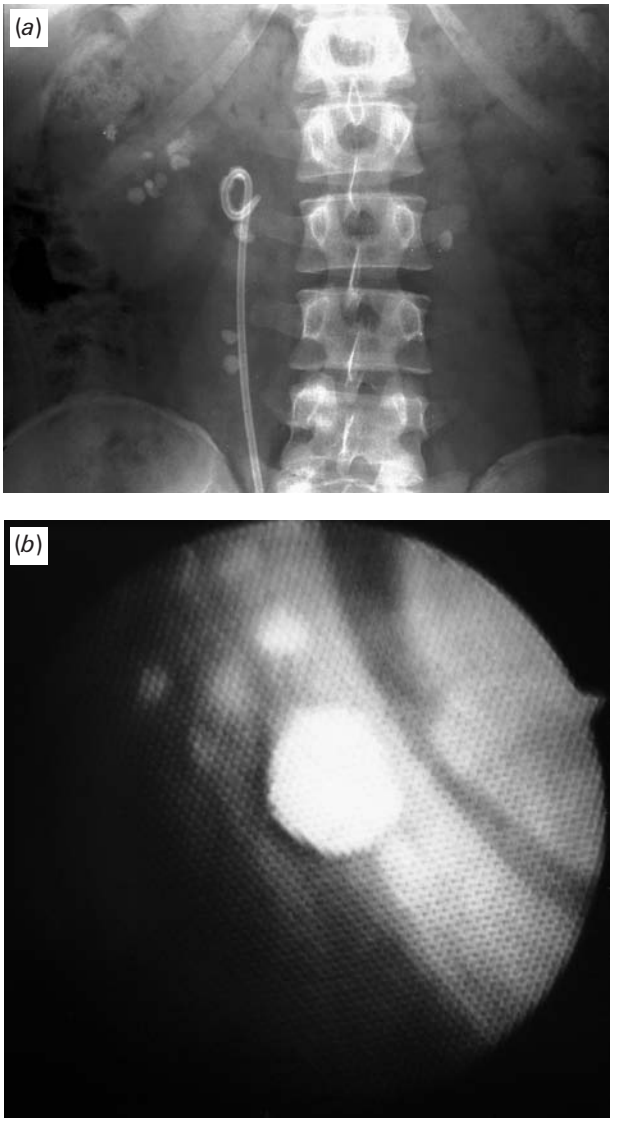

Figure 26.3 (*a*) A large stone burden is seen in both collecting systems in this teenage boy as well as encrustation of stone matter on the proximal portion of the pigtail stent. An underlying metabolic abnormality was suspected and, in fact, he had primary hyperparathyroidism. It is not uncommon to see papillary tip calculi (*b*) at the time of ureteroscopy for intrarenal calculi. These are seen as small areas of nephrocalcinosis on non-contrast CT scan. On metabolic urine evaluation, these children are more likely to show evidence of hypercalciuria.

of obstructive uropathy or urosepsis. It is important to have the child strain all urine so that calculus debris can be obtained and sent for stone analysis. This also gives an endpoint for conservative management, possibly eliminating the need for follow-up radiographic assessment.

Once the child has been cleared of any calculus disease, either through conservative management or surgical intervention, it is appropriate to obtain two consecutive 24-hour urine samples for metabolic stone analysis. These should include an internal creatinine standard to ensure completeness of urine sampling. Traditional urinary metabolic parameters include calcium, phosphate, magnesium, citrate, creatinine, uric acid, pH, and voided volume. For children not yet toilet trained, random urine measurements of creatinine, calcium, uric acid, and oxalate may be obtained, but preferably 2–4 hours after milk is ingested.[21] Pediatric reference ranges are now readily available and should be utilized.[2,21,22] Serum evaluation should be performed in children with stone recurrence or multiple calculi, and should include calcium, phosphate, uric acid, creatinine, sodium, and potassium. Surgical intervention is appropriate for any size stone with prolonged failure of spontaneous passage or unrelenting symptoms such as pain, nausea, vomiting, and gross hematuria. Proactive treatment of renal stones >5 mm should be considered, as a stone this size is likely to cause obstructive symptoms while passing through the urinary system. Treatment strategies should be based upon achieving the greatest stone-free rate for the particular situation, with the least morbidity and lowest risk for ancillary procedures. The most effective treatment plan may include multiple modalities.

Treatment options

Extracorporeal shock wave lithotripsy

Extracorporeal shock wave lithotripsy (ESWL) to treat pediatric stones was first reported in 1988.[23] Initial reports in animal models indicated evidence of significant renal damage following ESWL, which may have contributed to the delay in its use for children.[24,25]

Reported ESWL success rates after one session for mean stone sizes up to 2.5 cm are excellent, with a 75–98% stone-free rate at 3 months.[26–29] Ureteral stents are usually avoided after treatment for most stones, as children have an impressive ability to pass proportionately larger stone fragments than adults.[30,31] Initial experiences with ESWL monotherapy for staghorn calculi confirm the feasibility of this modality, with stone-free rates of approximately 75%.[32–34] These patients appear to benefit from pre-ESWL ureteral stent placement and often require ancillary procedures for complete stone clearance.[34]

Long-term functional studies on pediatric patients following ESWL now show no significant change in effective renal plasma flow or mean body height at least 4 years after treatment.[35–37] The safety and efficacy of ESWL have also been demonstrated in premature low birth weight infants.[10] Still, animal experimental studies demonstrating increased incidence and size of hematoma formation with increased number of administered shocks during ESWL require conservative use of this treatment modality.[38] Whereas extended long-term microvascular consequences and those on renal anatomy await elaboration in children, morphologic changes such as subcapsular or intrarenal hematomas have been infrequently noted. These findings usually resolve spontaneously within 1 week. It is not uncommon to see gross hematuria after ESWL, but this usually quickly resolves with increased fluid intake. Any child with significant abdominal or flank discomfort in the early postoperative period should be evaluated for possible hematoma or obstruction from calculus debris.

Hemoptysis has been reported postoperatively, particularly in children with significant orthopedic deformities.[39] Small stature and some skeletal deformities increase the risk of the pulmonary field being present within the shock wave path. Prevention of such a complication may be lessened through the use of styrofoam padding, and symptoms should resolve with conservative management.

Shock waves are generated and focused by a variety of mechanical systems. The original units are spark-gap generated, ellipsoid focused systems that are extremely powerful and have a wide focal point. The Dornier HM3 (Dornier MedTech, Kennesaw, Georgia) remains the gold standard in efficacy for stone fragmentation. However, the HM3 produces a wider area of shock wave effect and styrofoam sheets should be placed to protect the lungs, while gantry modification is required for smaller children.[10,40] Subsequent generations of lithotriptors have less scatter of energy, increased ease with which a child can be placed on the unit, and improved localization of radiolucent stones as a result of sonographic coordination. These improvements decrease the intensity of energy and exchange overall stone-free rates for potentially mini-

mized renal trauma. Newer-generation ESWL units are portable and may be easily transported between operating room suites. In adults it is possible to perform ESWL under light anesthesia, although children generally require a deeper general anesthetic for successful completion. Localization of the stone during treatment is determined by fluoroscopy, sonography, or plain X-ray films. Sometimes it is necessary to position a child prone in order to access the stone for effective lithotripsy.

Similar principles are applied for children as for adults, and proper patient selection will help to improve treatment outcomes. Some relative contraindications for ESWL include morbid obesity, a large stone burden, increased stone density, congenital skeletal/renal anomalies, and previously failed ESWL. The number of shocks, and the maximum energy level should be tailored for each case, and periodic stone visualization during the procedure will demonstrate when adequate lithotripsy has occurred. The primary goal is always to use the least amount of energy necessary to accomplish successful treatment.

Ureteroscopy

Advances in fiberoptics and in the design of mini rigid, semirigid, and flexible ureteroscopes has allowed for miniaturization of endoscopes and a resurgence of interest in endoscopy for pediatric patients. Adequate visualization has not been significantly compromised despite the downsizing of endoscopes. Digital imaging as well as enhancements in video technology allow for clear visualization as well as instantaneous documentation of endourologic procedures. Digital chips incorporated into larger flexible endoscopes currently exist, but technologic limitations prevent their use in the smaller-caliber instruments.

Pediatric ureteroscopy was first reported in 1929 by Hugh Hampton Young.[41] The procedure was performed on a 2-month-old boy with massively dilated ureters secondary to posterior urethral valves. Young utilized a 9.5 Fr pediatric cystoscope and was able to visualize the ureter as well as the intrarenal collecting system. But ureteroscopy gained gradual widespread acceptance by pediatric urologists only after Ritchey and Shepherd independently published articles on the technique of pediatric ureteroscopy for treatment of urinary calculi in 1988.[42,43]

Two types of ureteroscopes are available to the pediatric urologist: the mini rigid fiberoptic ureteroscope and the flexible fiberoptic ureteroscope. The mini rigid fiberoptic (i.e. semirigid) ureteroscope has a metal outer casing, which is malleable enough to allow for limited bending without image distortion. These endoscopes are more durable than flexible ureteroscopes and most can be safely autoclaved for sterilization. Excellent visual fields, and two working channels that allow for simultaneous irrigation as well as placement of working instruments, make these endoscopes particularly useful in the distal ureter. However, passage into the proximal collecting system above the bony pelvis may be difficult. Varying lengths are available, and the authors use both a 15 cm and 33 cm endoscope tailored to the child's size and location of the stone (Figure 26.4) Although the distal tip is as small as 4.7 Fr, the gradual increase in the diameter of the malleable metal shaft proximally towards the eyepiece requires one to maintain vigilance to minimize the risk of meatal injury in the young male.

Flexible ureteroscopes are useful within the proximal and intrarenal collecting system due to their active as well as passive tip deflection. Some models have the capability of both primary and secondary active deflection (DUR-8 Elite, Circon ACMI, Southborough, MA) and others have 270° primary deflection in either direction (Flex-ex, Karl Storz, Tuttlingen, Germany). Most flexible ureteroscopes have a working channel of approximately 3.6 Fr, which is adequate for passage of instruments while maintaining space for irrigation. Rarely, however, is secondary passive tip deflection necessary for complete inspection of the intrarenal pediatric collecting system because the arc of deflection is adequate to access the lower pole in most pediatric kidneys. Many working instruments will decrease the ability to actively deflect the ureteroscope, and it is important to remember to straighten the distal tip of the ureteroscope prior to passage of any working instrument to help prevent damage to the working channel.

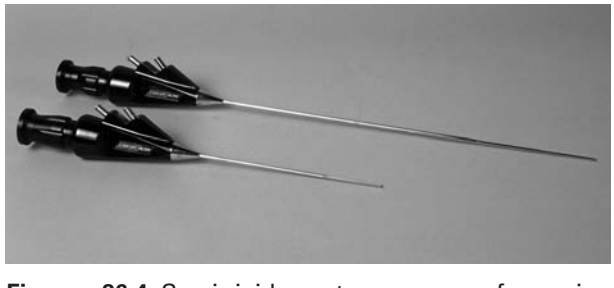

Figure 26.4 Semi-rigid ureteroscopes of varying lengths are most helpful for stone removal within the mid and distal ureter. The two separate lumens permit continuous irrigation through one port while performing tasks through the second port.

Resistance within the working channel may be decreased through the use of a silicone lubricant.

Recent technologic advancements have improved the durability of both the outside sheath, and deflecting mechanisms, but have resulted in an increased outer diameter. Because of their flexible design, these endoscopes are more prone to damage and need to be handled with care. Replacement of the fiberoptic bundles is necessary when the image becomes significantly distorted, and any perforation of the working channel will cause damage to the endoscopes. Flexible endoscopes can be safely soaked in cold sterilization solution or undergo gas sterilization, but cannot be autoclaved. The distal tip is approximately 7.4 Fr but gradually becomes 8.5 Fr or greater at the proximal shaft, which helps to strengthen the sheath and protect the inner bundle fibers. The authors prefer the use of three distinct lengths in children (35, 50, and 65 cm) in order to decrease the amount of redundant shaft outside of the body, which helps to prevent damage during use (Figure 26.5).

Working instruments

A variety of working instruments have been designed for use within miniaturized endoscopes. Guidewires are required as a platform for advanced ureteroscopy and are the most commonly used working instruments in endourology: not only do they aid in access to the ureter but also they help to prevent intraoperative complications by preventing loss of access to the collecting system. Most guidewires have an inner stainless steel core coated by polytetrafluoroethylene (PTFE) to reduce friction, and others have a superelastic nitinol (nickel–titanium) alloy core, which prevents kinking of the wire. There are varying diameters, but a 150 cm PTFE-coated guidewire with a 3 cm floppy distal tip is the most common type in our practice. The distal tip may be straight or angled and the length of its flexible floppy tip varies. A wire with a floppy tip on both ends is the safest choice for passage of a flexible ureteroscope because it minimizes potential damage to the working channel.

A hydrophilic-coated guidewire is helpful for negotiating a tortuous or narrowed ureter and for placement of a working wire proximal to an impacted ureteral calculus. These extremely slippery guidewires need to be kept moist and should not be used as safety wires, because of the ease with which they may be dislodged during an endoscopic procedure. Handling of the slippery hydrophilic wires is made easier through the use of a moistened gauze sponge. For straightening tortuous or reimplanted ureters, extra stiff guidewires may be used, and these should also be used for percutaneous tract dilatation. Importantly, these wires should not be used when placing a flexible ureteroscope because of the increased risk of damaging the delicate working channel.

Development of a wide spectrum of accessories, from stone baskets to grasping forceps, has significantly aided the extraction of stone debris from the collecting system. The instruments vary in diameter from 1.9 to 4.5 Fr and most are contained within a hydrophilic sheath (PTFE, polyimide) to facilitate passage.

A variety of designs of baskets exist, but the most significant improvement in basket design has been the tipless nitinol basket. The tipless design makes it particularly safe and useful for extraction of stones within a tight calyx (Figure 26.6) and, when deployed,

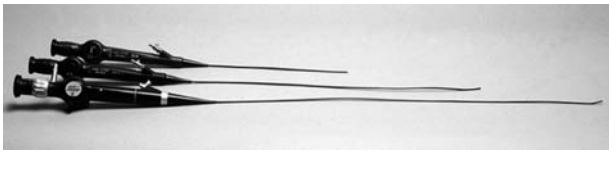

Figure 26.5 Flexible ureteroscopes are much more prone to damage because of their delicate design. To decrease this risk, it is helpful to have multiple lengths available, in order to eliminate redundancy of the endoscope outside of the body during the procedure.

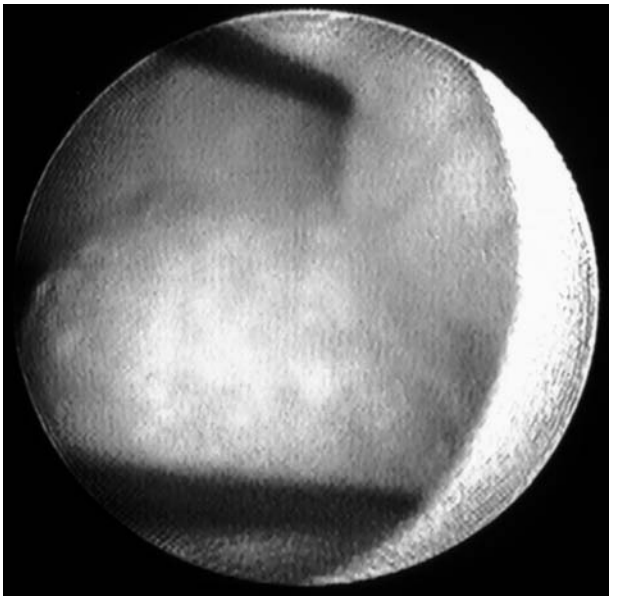

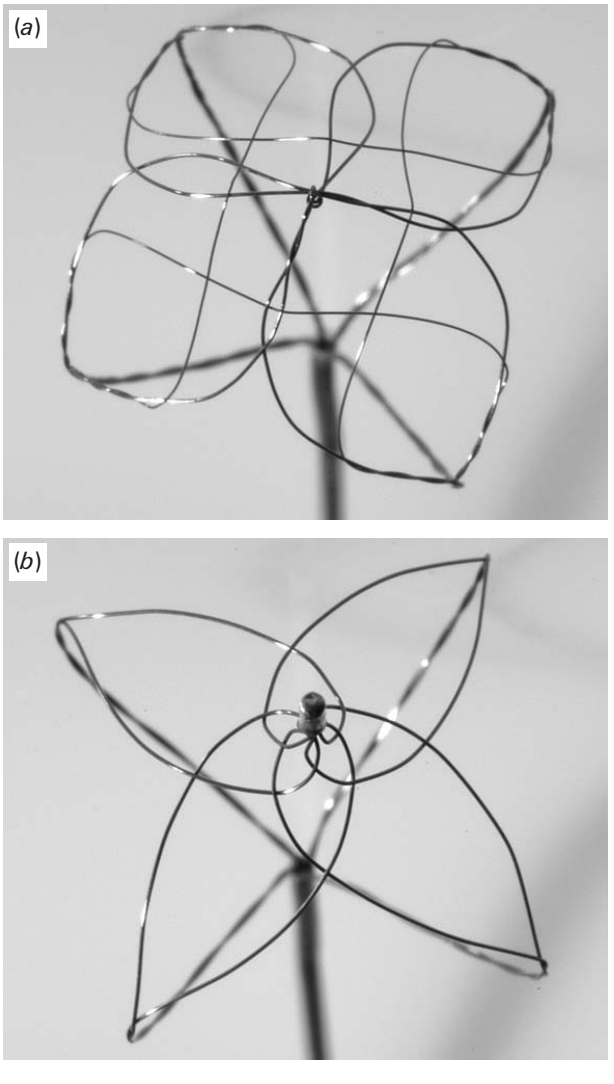

Figure 26.6 The small, tipless nitinol baskets enable removal of stones contained within tight calices with minimal trauma.

allows for more complete active deflection of the ureteroscope due its increased flexibility.[44] Some of the newer baskets have been designed to allow controlled active angulation of the baskets' wires (Dimension, Bard Urological Division, Covington, GA) and others enable a canopy to form that may engage multiple small calculi (Figure 26.7). Multi-sizing baskets omit the need for stocking multiple basket sizes, and some baskets have a central channel that allows for the simultaneous placement of electrohydraulic or laser lithotripsy probes once the stone is stabilized.

Grasping forceps are quite helpful during endoscopic stone extraction, particularly within the ureter, and, indeed, are the authors' preferred instruments in most cases (Figure 26.8). The most significant advantage is that a grasper will disengage from a stone if it becomes lodged within a relatively narrow ureteral segment. This helps to prevent trauma of the ureteral wall by eliminating entrapment during stone removal. The grasper should be opened only as wide as is needed to engage the stone, thus decreasing the risk of ureteral wall perforation (Figure 26.9). It is important to maintain contact with the stone while closing the graspers; therefore, slight advancement of the sheath is needed as the forceps are closed.

Proper selection of a stone retrieval device is important for the successful and timely completion of any endoscopic procedure. Several factors impact this decision – particularly, the size, position within the collecting system, and condition (i.e. impacted vs non-impacted) of the stone. Ptashnyk et al studied ex-vivo porcine kidneys and ureters to determine which stone retrieval devices were most effective in certain situations.[45] Their conclusions were that graspers are most efficient at the removal of a single ureteral stone (particularly impacted) with little mucosal damage,

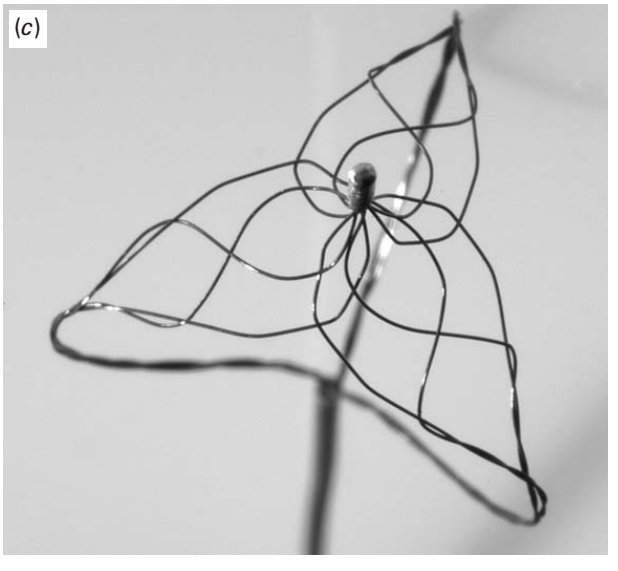

Figure 26.7 (*a–c*) The various configurations of other nitinol baskets enhance the retrieval of small particles remaining after laser lithotripsy. Some of these baskets have a central channel that allows for the placement of lithotripsy devices after stone entrapment. Always proceed cautiously when removing multiple stone fragments because the caliber of the ureteral lumen may be inadequate to allow for safe retrieval. (Courtesy of Cook Urological, Spencer, IN.)

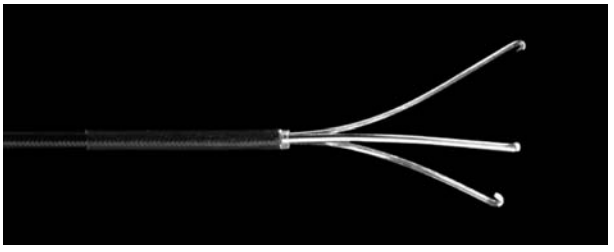

Figure 26.8 Grasping forceps are strong enough to dislodge embedded papillary calculi and delicate enough to disengage a stone if it becomes lodged within a narrow ureteral segment. (Courtesy of Cook Urological, Spencer, IN.)

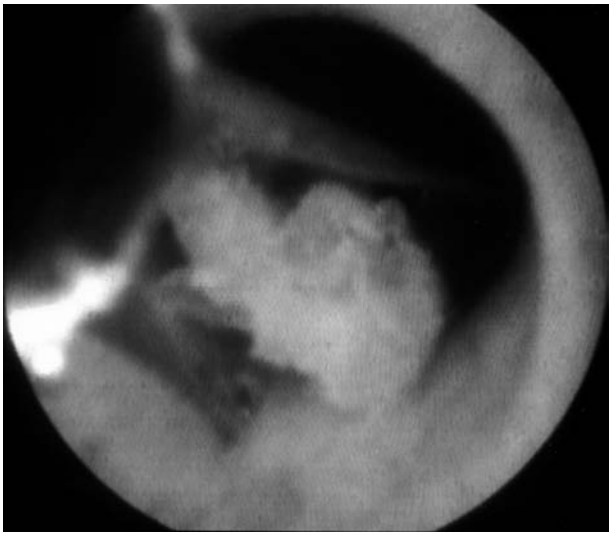

Figure 26.9 To prevent ureteral wall perforation, it is important to open the grasper only as far as needed to encompass the lateral aspects of the stone. This will also help to prevent the inadvertent grasping of the ureteral wall, which would probably result in ureteral trauma.

and that a helical basket was most effective for Steinstrasse. In another study, nitinol baskets have been shown to be most effective for caliceal stones and those in the lower pole.[46] The flexible nitinol component and the atraumatic tipless basket design allow complete deflection and produce minimal surrounding tissue trauma.

A newer instrument is the Dretler stone cone (Microvasive, Boston Scientific, Natick, MA), which is an 0.038 inch nitinol Teflon-coated wire that can be coiled proximal to the calculus acting as a backstop to prevent proximal migration. It has been shown to be effective in extracting stone fragments and more successful than flat-wire baskets in preventing stone migration.[47]

Intracorporeal lithotripsy

Historically there are four modes of intracorporeal lithotripsy:

- ultrasonic lithotripsy
- ballistic (i.e. pneumatic) lithotripsy
- electrohydraulic lithotripsy (EHL)
- laser lithotripsy.

Each has been extensively studied, and all have unique capabilities and limitations.

Ultrasonic lithotripsy was first described 1953.[48] The metal probe transmits vibrational energy to the tip, which, when in contact with the stone, results in disintegration due to cleavage of the crystal matrix. Small solid probes can be utilized through pediatric cystourethroscopes and large probes with a central suction channel are helpful for removal of stones during percutaneous procedures (Figure 26.10). These probes will lose energy transmission with any degree of bending, and, therefore are most effective when used in endoscopes with a straight working channel. Ultrasonic lithotripsy is safe and results in minimal tissue damage.[49] It is best suited for the percutaneous treatment of large renal stones.

Ballistic lithotripsy involves the pneumatic mechanical impaction of stones by a solid probe. There are no thermal or cavitation effects; therefore, risk of tissue injury is minimal. This modality has been effective in fragmenting all types of stones and smaller flexible probes are available.[50–53] Retrograde migration due to pneumatic impaction as well as loss of lithotripsy power, with significant deflection of the probe, are two significant shortcomings.

EHL was discovered by Yutkin in 1955 and

Figure 26.10 Ultrasonic lithotripsy probes can be used in straight-channel endoscopes and are most helpful during the percutaneous removal of staghorn calculi. (Courtesy of Circon ACMI, Southborough, MA.)

involves the generation of an electrical spark, which produces a cavitation bubble, providing sufficient energy to produce lithotripsy.[54] The energy is maximal at a distance of approximately 1 mm from the stone and therefore the tip of the probe should be kept just off the surface of the stone. Electrohydraulic lithotripsy may not fragment all stone compositions but is able to be used through both flexible and rigid endoscopes. One significant risk of EHL is lateral dissemination of the energy, which can increase injury to the surrounding soft tissues. Probes are as small as 1.9 Fr, which will allow access to lower pole calculi.

Holmium:yttrium–aluminum–garnet (Ho:YAG) laser lithotripsy is extremely effective at fragmenting all types of urinary calculi[55] and has become the preferred modality for stone fragmentation at our center (Figure 26.11). Holmium laser lithotripsy was first reported in 1992[56] and subsequent reports have shown it to be safe in adults and children.[57,58] Holmium lithotripsy involves direct stone absorption of laser energy, with subsequent disintegration.[59] Solid quartz fibers as small as 200 μm enable near complete deflection of a flexible ureteroscope, providing access to nearly all parts of the collecting system. The laser fiber is placed near the stone in order to result in fragmentation. Larger fibers are helpful in the disintegration of larger stones contained within the kidney or bladder. It is essential that the surgeon maintain direct visualization of the tip of the probe to prevent subsequent endoscope or tissue damage during use. Holmium laser lithotripsy results in dust particles and fragments <2 mm, which should be able to pass spontaneously.

Figure 26.11 Holmium laser lithotripsy is safe and the most effective at breaking apart calculi. The precise delivery of energy allows the surgeon to smooth rough edges from a spiculated calculus, and to specifically cleave larger stones into distinct fragments for subsequent removal.

Ureteroscopy technique

Ureteroscopy in children requires general anesthesia. After being placed in the dorsal lithotomy position, the child is well padded to prevent excessive limb abduction or a compartment syndrome. The male urethral meatus is carefully inspected and gently dilated if necessary. Cystoscopy is performed to inspect the bladder and visualize the position of ureteral orifices. A urine sample is obtained at the time of the cystoscopy and sent for urine culture.

The authors first gauge the caliber of the ureteral orifice by using an 0.035 inch guidewire (Figure 26.12). The ureter has three physiologic areas of narrowing, with the narrowest portion being the orifice. These anatomic differences are age dependent, based on work by Cussen in 1971.[60] For practical purposes, if the orifice appears 'volcanic' and barely accepts an 0.035 inch guidewire, then either active dilatation or prestenting of the ureter is performed. It is sometimes helpful to gain access to the ureteral orifice using two guidewires, one inside the working channel and the other already independently placed in the ureter as a safety wire (Figure 26.13). This helps to control access

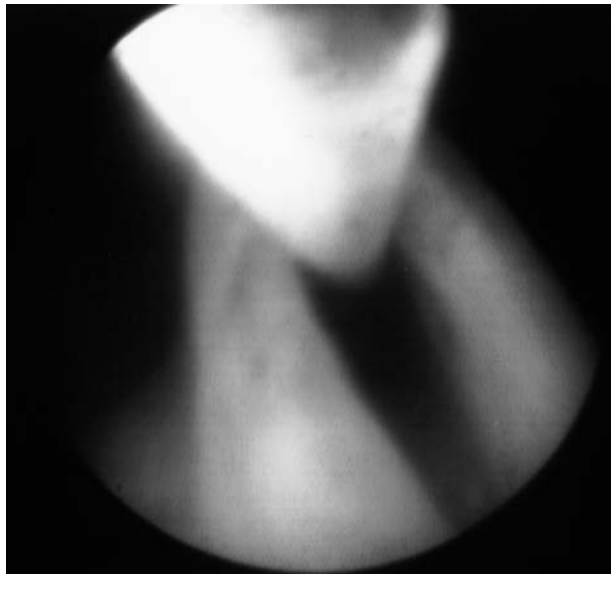

Figure 26.12 An 0.035 inch Teflon-coated guidewire is used to gauge the ureteral orifice at the beginning of a ureteroscopy procedure. If a gap is created with tenting up the ureteral lip, then a semirigid ureteroscope can usually be guided into the ureter without active dilatation. A volcanic-appearing orifice should be prestented to allow for subsequent passive dilatation.

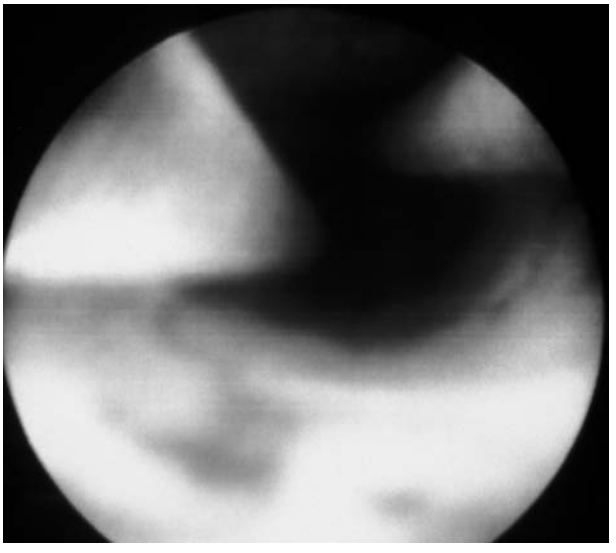

Figure 26.13 One helpful technique during difficult access is placing a second guidewire through the working channel of a semi-rigid ureteroscope after having placed a safety wire within the ureteral lumen. This will sometimes facilitate advancement of the ureteroscope by spreading the ureteral orifice.

and to increase the diameter by placing the endoscope directly between the two wires. If dilatation is needed, the authors' preference is to use a graduated single-shaft dilator, which ranges from 6 to 10 Fr (Figure 26.14). Dilatation to 2 Fr sizes greater than the diameter of the endoscope is usually needed for successful access (Figure 26.15). Dilatation can be facilitated by performing this over a stiff guidewire or through a 13 Fr cystoscope sheath in order to prevent buckling within the bladder. Reports of balloon dilatation to 15 Fr have previously shown no significant complications or reflux, but clearly produce more active dilatation than actually necessary. If these maneuvers do not allow easy dilatation or access of the ureter, the authors believe it is more prudent to place a ureteral stent to passively dilate the ureter rather than to perform significant active balloon dilatation. Dilatation of the ureter may be required in approximately 30% of children undergoing ureteroscopy.[61]

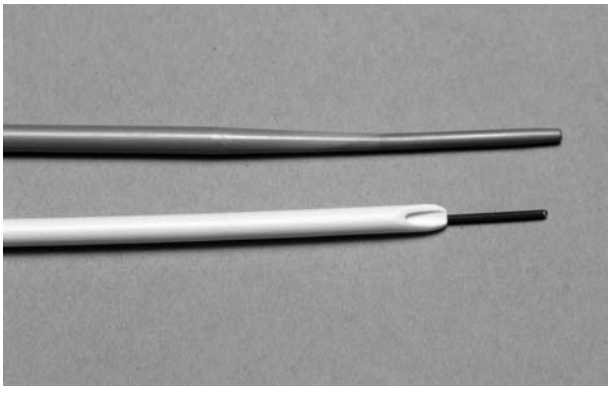

Figure 26.14 Controlled active dilatation can be performed using a soft graduated dilator (top) over a stiff guidewire. A dual-lumen catheter (bottom) is helpful when placing a second working wire and also for instillation of contrast material.

Figure 26.15 Dilatation is required if the semi-rigid endoscope cannot be placed directly into the ureteral orifice. If access is unsuccessful because of an impacted stone (*a*), dilatation will be needed (*b*) after establishing proximal control. In (*b*), the stiff guidewire has been removed and will be replaced with a standard Teflon-coated safety wire.

When therapeutic maneuvers are anticipated, it is important to maintain a safety guidewire within the ureter. As mentioned previously, a hydrophilic guidewire may aid in accessing a tortuous ureter or one with an impacted stone, but should not be used as a routine safety wire, because of the ease with which it may become dislodged. A flexible ureteroscope requires either the use of an access sheath or a second working guidewire for placement of the ureteroscope into the proximal collecting system (Figures 26.16 and 26.17). The smallest sheath that accepts flexible ureteroscopes is 9.5 Fr; therefore, in small children, prestenting of the ureter is often required in order to dilate the ureter to allow the safe use of an access sheath. Access sheaths should be used with caution and are most helpful when it will be necessary to traverse the ureteral orifice many times when treating large or multiple stones in the proximal collecting system. Fluoroscopic guidance is absolutely necessary during any ureteroscopic procedure.

Figure 26.16 Placement of a flexible ureteroscope into the proximal collecting system is most often accomplished using a monorail technique, by guiding the scope over a wire. A second safety wire is necessary when therapeutic intervention is anticipated.

Figure 26.17 Access sheaths are quite helpful when removing large stone burdens from either the proximal ureter or the intrarenal collecting system. Placement of this sheath is made easier by prestenting the ureter or when working in a dilated collecting system. When removing stone fragments, it is important to make certain the ureteral mucosa does not get trapped between the stone and the proximal lip of the sheath. (Courtesy of Cook Urological, Spencer, IN.)

Previous urologic surgery involving either the bladder neck, ureter, urethra, or ureteropelvic junction is not necessarily a contraindication to ureteroscopy. Also, the authors have performed intrarenal ureteroscopy in an 11-month-old male infant with significant congenital ureteral 'valves'. A child who has undergone previous hypospadias surgery may require urethral dilatation prior to placement of the ureteroscope if there is meatal stenosis. It is important to use small-diameter endoscopes to avoid disruption of previous bladder neck reconstruction. Often, children who have had bladder neck reconstruction have had ureteral reimplantation at the time of their primary surgery, and care must be taken not to significantly distort the bladder neck when accessing the previously reimplanted ureter. Access to the ureter after previous reimplantation is clearly dependent upon the type of surgery performed. When either an advancement or extravesical procedure has been utilized, access is similar to the unoperated child. When a previous cross-trigonal reimplantation has been performed, access can be more difficult. In this instance, the ureteral orifice is usually laterally located and can be cannulated with an angled guidewire. If this maneuver is unsuccessful, an actively deflecting guidewire can be utilized. Once access has been gained, the initial wire should be replaced with a stiff guidewire, which then straightens the intramural portion of the ureter, allowing access for ureteroscopy. Dilatation of the tunnel is usually not necessary, although it is sometimes necessary to dilate the ureteral orifice. When the procedure is finished, the ureter will return to its preoperative cross-trigonal position. Recurrent reflux after ureteroscopy in the previously reimplanted ureter has not been demonstrated.

Intrarenal access after previous ureteropelvic junction (UPJ) repair is usually straightforward as long as there has been adequate healing and success of the previous surgery. The ureter remains supple at the site of previous repair and is at no greater risk of injury. Postoperative stenting is not always required after distal stone removal, or ureteroscopy in a prestented child, but should be performed after procedures requiring either extensive manipulation, significant active dilatation, or work within the proximal collecting system. If a stent is left in place, a 'dangler' string

is used to facilitate removal without anesthesia in the office approximately 1 week after the procedure.

A semi-rigid ureteroscope should be used for distal and midureteral calculi (Figure 26.18). The instrument may be used for more proximal stones if it can be successfully passed above the pelvic brim. Flexible ureteroscopy is necessary most of the time for proximal ureteral calculi and should always be used for stones contained within the intrarenal collecting system (Figure 26.19). Complete access to the intrarenal system is usually accomplished through active deflection alone; rarely, is secondary passive deflection necessary in the smaller pediatric kidney. Installation of contrast during ureteroscopy will provide a guide during the complete inspection of the collecting system under fluoroscopy.

Once the stone is encountered, it is important to gauge the size of the stone versus the diameter of the ureter. Many ureteral stones can be removed intact through basket or grasper manipulation, provided the caliber of the distal ureter is adequate to allow atraumatic retrieval. For impacted stones, or those too large to remove intact, in-situ holmium laser lithotripsy is performed. For an impacted stone, attempts should be made to dislodge the stone into the proximally dilated portion of the ureter. This will allow more room for laser lithotripsy, and decrease the risk of complications. Once the stone is dislodged, the jagged surface is either precisely treated to smooth out rough edges or the entire stone can be cleaved into distinct fragments for subsequent removal. Stones that cannot be dislodged should be treated first on the periphery, which should help to disimpact the stone. It is desirable to retrieve at least one stone fragment for crystallographic analysis, and once this is achieved it is more efficient to deposit subsequent small fragments within the bladder to pass spontaneously. If a stone fragment becomes displaced outside the ureteral wall due to perforation, further attempts at extraction should be abandoned.

Figure 26.18 A semirigid ureteroscope is the instrument of choice for removal of distal and mid ureteral calculi. It can be utilized for proximal stones if the endoscope can be safely guided into the proximal collecting system. Care should be taken to ensure that the urethral meatus in young boys is not damaged by the increased diameter of the proximal shaft of any endoscope.

Percutaneous endourology

Thomas Hillier in 1865 is credited with the description of the first therapeutic percutaneous renal drainage of what was described as ureteropelvic junction obstruction.[62] Unfortunately, after 4 years of periodic percutaneous drainage, the young boy succumbed to septicemia at age 8. It wasn't until 1941 that Rupel described the removal of renal calculus debris through a nephrostomy tract using endoscopic equipment.[63] Percutaneous drainage of hydronephrosis was subsequently reported by Goodwin in 1955,

Figure 26.19 Flexible ureteroscopy is necessary for the removal of intrarenal calculi. Passive secondary deflection is rarely needed to gain access to the lower pole of the pediatric collecting system because of the arc of deflection.

but it wasn't until 1985 that Woodside et al presented a series of seven pediatric patients who had undergone a percutaneous procedure.[64]

In the early days of the procedure, percutaneous stone removal was limited to children ≥ 8 years old because of fears of significant blood loss and increased renal damage with large (>24 Fr) tract dilatation.[65] The defect created by a 24 Fr tract in a child's kidney corresponds to a 72 Fr defect in an adult kidney.[66] Increased tract size is directly correlated with increased complication rates, although no significant renal scarring or functional changes can be readily detected after large tract dilatation.[67,68] Subsequent reports have demonstrated that percutaneous procedures are technically feasible for children <8 years old, and that complications can be decreased by utilizing a tract <22 Fr.

Because of concerns regarding hematologic complications, the technique of a smaller-access percutaneous procedure has been developed. Helal et al presented their experience using a 15 Fr peel-away sheath in a 2-year-old child for percutaneous stone removal.[69] A smaller 11 Fr technique using a 'mini-perc' approach has also been reported, and a purpose-built access kit is available.[66] Access to the collecting system is thought to be less traumatic because of the smaller caliber site. There have been no reports of bleeding complications in uncomplicated procedures after mini-perc intervention, and the need for postoperative percutaneous nephrostomy drainage is often eliminated. Treatment of large (>3 cm) stones can be tedious; therefore, a larger peel-away sheath (15–22 Fr) is recommended to expedite stone fragment removal.

Most pediatric percutaneous procedures are performed for management of renal calculi. It is important that these procedures be performed in an institution where there is an endourologist and interventional radiologist experienced in the treatment of children. Needle access to the kidney is required for tract dilatation and therapeutic intervention, and there is some suggestion that obtaining early access (1 day prior to surgery) may decrease bleeding as well as operative time. This is particularly helpful for a mini-perc procedure because the smaller field of view becomes easily obscured by minimal bleeding. Nevertheless, it is possible to obtain access at the time of percutaneous intervention, which does in most cases result in safe completion of the procedure.

The proper site for percutaneous access should both allow a direct route to the stone and permit easy access to other areas of the collecting system. The optimal position is usually a posterior calyx with a wide, straight infundibulum. Multiple sites may be necessary, and should be utilized when there is a complete staghorn calculus or any intrarenal anomalies making it difficult to access all stone-containing calices through a single site. Bleeding requiring transfusion is not increased when multiple sites are utilized.[70] It is important to obtain the primary access site where it will be possible to maximally debulk the stone burden, and secondary sites where calices will be difficult to reach through the primary tract. If the stones are contained within a caliceal diverticulum or a calyx with a narrowed infundibulum, it is necessary to have direct access into that part of the collecting system. Upper pole access sites should be used with caution because of the increased risk of pneumo/hydrothorax. Consequently a chest X-ray should be obtained at the conclusion of any percutaneous procedure involving upper pole access.

Once needle access has been obtained, a wire is passed down the ureter into the bladder to allow a controlled tract dilatation and to avoid the accidental loss of access to the collecting system. Slippery hydrophilic guidewires should be exchanged for standard PTFE-coated wires prior to dilatation. The use of a stiff guidewire will facilitate dilation. If ureteral access is not possible or if access is obtained into an obstructed system or caliceal diverticulum, multiple coils of the wire should be placed within the contained collecting system prior to tract dilatation.

Once safe access has been confirmed, if mini-perc access is not to be used, the tract is dilated either using sequential graduated dilators (Amplatz) or active balloon dilatation (Figure 26.20). Both techniques have been proven safe and efficacious, but sequential dilatation of larger tracts may increase the risk of bleeding owing to the potential shearing effect of this technique. Constant vigilance under fluoroscopy is necessary to avoid disruption of the renal pelvis. The small non-dilated pediatric kidney is at greatest risk for this

Figure 26.20 Percutaneous balloon dilators come in a variety of sizes. They need to maintain high radial pressures in order to dilate the fascia. The access is placed into the collecting system over the balloon after partial deflation. (Courtesy of Cook Urological, Spencer, IN.)

complication, and extreme caution must be undertaken to help prevent such occurrences. If there is significant disruption of the renal pelvis or UPJ, it may be necessary to abandon the procedure and to place a temporary nephrostomy or nephroureteral stent.

For balloon dilatation, the distal radiographic marker is placed into the renal pelvis, while the proximal portion of the balloon is located externally. The balloon is then inflated to its maximum pressure and then left fully inflated until there is no longer any evidence of fascial constriction (Figure 26.21). The balloon is kept inflated for several minutes to help aid in hemostasis. The access sheath can be placed into the pelvis over the balloon once it has been partially deflated. The balloon size should correlate with the size of the sheath to be used.

If there is any significant bleeding encountered after dilation, it may be necessary to temporarily place either a large Foley catheter or a tamponade balloon. If these techniques do not result in satisfactory hemostasis, it will be necessary to leave the catheter in place and perform the therapeutic intervention at another time. Uncontrolled hemorrhage requiring transfusion should be evaluated with angiography for possible vascular embolization.

After the working sheath has been placed, the planned procedure is undertaken. Both rigid as well as flexible instrumentation may be necessary and should be present in the operating room suite in case the need arises. If there is a large stone burden, the procedure will be facilitated through placement of a 22 Fr sheath. This allows access with an adult nephroscope, enabling the use of larger instruments, and the capability of removing large intact stone fragments. If a mini-perc procedure is performed through an 11 Fr peel-away sheath, then either an offset pediatric cystoscope with a straight working channel or a 9.5 Fr modified mini rigid ureteroscope will be necessary to access the kidney. The straight-channel offset lens endoscope will allow for the passage of ultrasonic and ballistic lithotripsy probes, whereas the in-line mini rigid cystoureteroscope will require the use of the holmium laser, electrohydraulic, or flexible ballistic lithotripsy devices for stone fragmentation. The authors like the in-line endoscope because it has two working channels, which facilitates simultaneous suction irrigation (5.4 Fr) and lithotripsy (2.3 Fr). (Figure 26.22) It also permits 360° rotation of the endoscope for maximum positioning of lithotripsy probes. The endoscope used should be several French

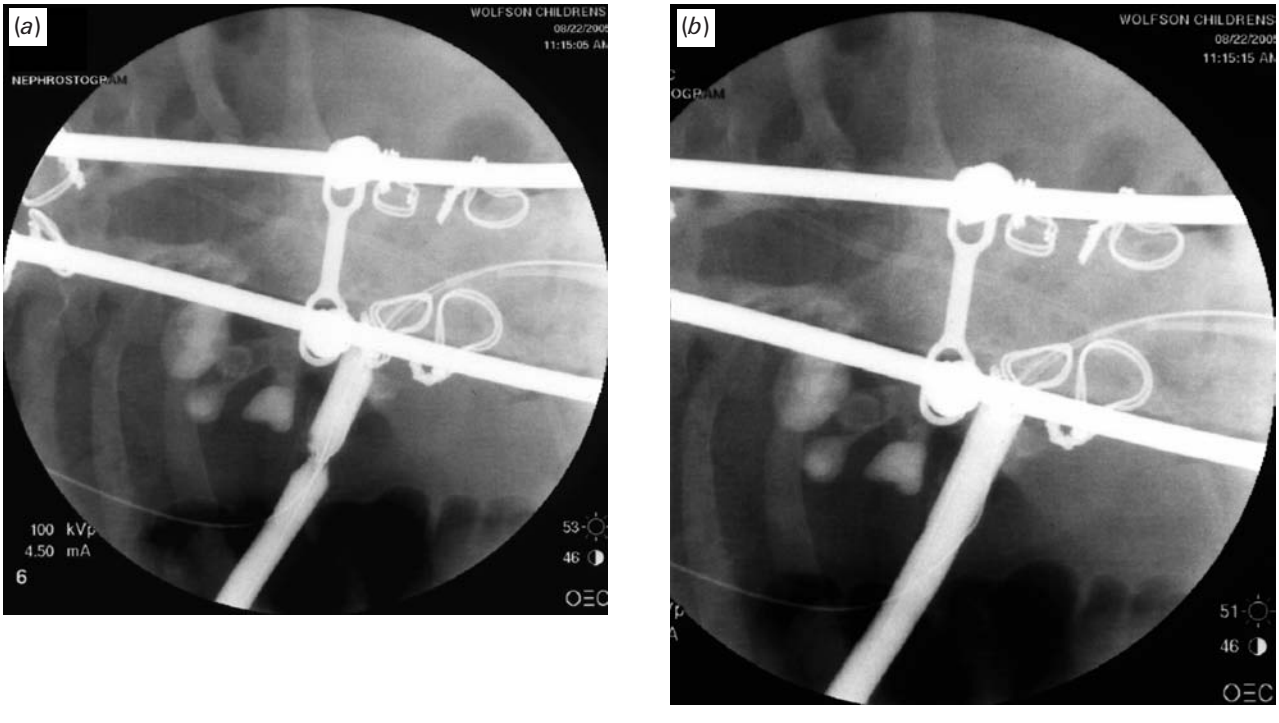

Figure 26.21 After proper positioning under fluoroscopy has been confirmed, contrast is used to expand the percutaneous balloon dilator under fluoroscopy. Initial fascial constriction (*a*) is noted, and the balloon is inflated to its maximum pressure until all constriction has been eliminated. (*b*) The size of the balloon should be slightly larger than the sheath to be utilized.

Figure 26.22 The mini-perc procedure requires the use of a small-caliber endoscope. A modified straight semi-rigid ureteroscope with two working channels is helpful because it allows for 360° rotation and also permits simultaneous lithotripsy and irrigation. (Courtesy of Circon ACMI, Southborough, MA.)

sizes less than the internal diameter of the sheath in order to allow continuous flow around the scope, which lessens the risk of significant extravasation. The use of warmed saline irrigant is encouraged, which will need to be changed to water or glycine if an electrosurgical procedure is planned. Note that this does not include EHL, which is effective in saline. The potential for dilutional hyponatremia in infants and children is significant, and therefore saline should be used whenever feasible. Levering of the nephroscope should be limited in order to avoid injury to the infundibulum, as well as the renal parenchyma, during the percutaneous procedure.

Endourologic instrumentation is similar to that used for other procedures. The holmium laser is particularly useful during small-caliber percutaneous access procedures in order to debulk large stone burdens. Extraction of stone fragments is facilitated by using a 4.5 Fr nitinol basket. Ultrasonic lithotripsy is quite safe and can be performed through the straight working channel of either a small-caliber offset cystourethroscope or an adult percutaneous nephroscope. Attempts should be made to remove all stone fragments >2 mm in order to limit a potential nidus for stone regrowth or obstruction with passage of a large fragment. Complete visualization of the intrarenal collecting system, as well as the ureter, should be undertaken. This usually requires the use of a flexible endoscope and should be undertaken prior to completion of the planned procedure. Complete inspection is sometimes hampered by limitations of the size of the pediatric kidney and the size of the percutaneous access sheath. Significant clots may obscure stone fragments; therefore, every attempt should be made to irrigate them free to allow complete visualization. Most of the time it is necessary to leave a percutaneous nephrostomy tube in place at the completion of the procedure, but it is possible to limit its use. Access to the kidney should be maintained until postoperative X-rays confirm that no second-look procedure will be needed.

Treatment strategies

Many factors need to be considered when deciding the proper treatment modalities for urinary tract calculi in children. Not only are the characteristics of the stone (size, shape, location, density, number, etc.) considered but also the characteristics of the child. Body habitus, as well as associated congenital and acquired conditions, need to be taken into consideration. Surgeon expertise and available technology may also guide treatment strategy. Each case needs to be individualized in order to choose the best form of treatment: shockwave lithotripsy vs retrograde ureteroscopy vs an antegrade percutaneous approach.

Renal calculi

ESWL is the least-invasive form of therapy, and offers reasonable stone-free rates of >80% with minimal complications.[71–77] Stones that are ≤1 cm are most efficaciously treated by this modality and often require a single treatment (Figure 26.23). Higher retreatment rates and the need for ancillary procedures are seen with large stone burdens and in children with renal or collecting system abnormalities.[77,78] Therefore, ESWL is not the best therapy when there is evidence of UPJ obstruction, caliceal diverticulum, or infundibular stenosis (Figure

Figure 26.23 Stones that are ≤ 1.5 cm and do not appear extremely dense on X-ray, are best suited for ESWL.

Figure 26.24 Renal stones associated with congenital urinary tract anomalies should be treated by either ureteroscopy or percutaneous access. Mid or upper pole caliceal diverticula with small stone burdens can be effectively treated using flexible ureteroscopy.

26.24). ESWL is also less effective for ectopic and horseshoe kidneys because of difficulties with precise energy delivery (increased surrounding bony and soft tissue structures) and the presence of an abnormally rotated collecting system which may prevent post-treatment stone clearance. In addition, alternative therapies to ESWL should be considered for extremely dense stones (brushite, cystine)[79] and those calculi within an abnormal lower pole (i.e. long, narrowed infundibulum). In these instances the energy may not be sufficient for adequate lithotripsy, and the abnormal intrarenal anatomy may promote fragment retention. Currently, it appears that ESWL is best suited for solitary renal stones ≤1.5 cm that are not contained within an abnormal lower pole calyx and are not associated with any congenital or acquired renal abnormalities. Nevertheless, ESWL monotherapy for the treatment of staghorn calculi has been shown to be effective, with stone-free rates of approximately 88% after multiple treatment sessions.

The role of ureteroscopy for the treatment of renal calculi in children remains to be defined. Several reports have demonstrated ureteroscopy to be an effective treatment for stones throughout the entire intrarenal collecting system. It has been successful for the treatment of stone-containing caliceal diverticula of the mid and upper pole.[80] Primary ureteropyeloscopy with stone removal should also be performed when ureteroscopy is being used to treat other ureteral stones. This enables easy access to the kidney for treatment and provides the greatest chance of success with one procedure. Residual fragments after ESWL, or failure of ESWL as the primary procedure, are two other reasons to perform ureteropyeloscopy for stone removal. As mentioned previously, placement of a ureteral access sheath in a prestented ureter may facilitate removal of large stones. Concomitant UPJ or intrarenal obstruction can also be treated endoscopically at the time of stone removal.

For intrarenal stones >1 cm, multiple large calculi, staghorn calculi, or children with urinary tract malformations or a previous reconstruction, a percutaneous approach may be preferable. Stone-free rates after a single percutaneous session range anywhere from 70 to 100%.[67,81–85] For large stones and staghorn calculi, combined 'sandwich' therapy (percutaneous stone removal followed by ESWL), provides stone-free rates >90% (Figure 26.25). A percutaneous procedure does carry the risk of bleeding

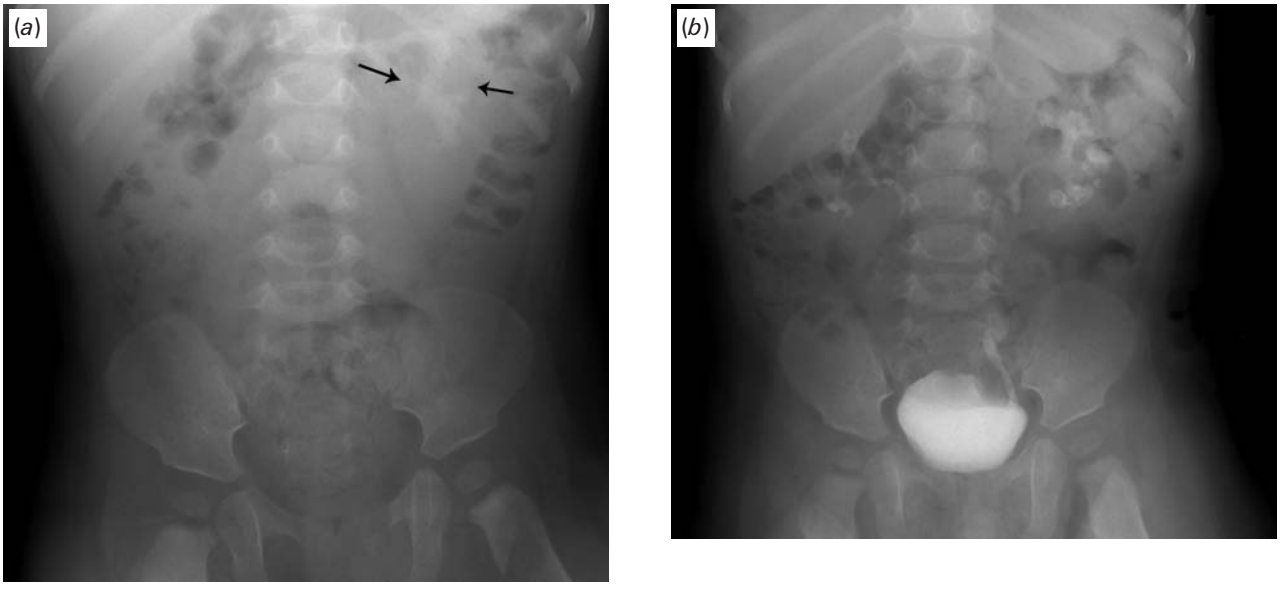

Figure 26.25 (*a*) A KUB in this 11-month-old girl who had been having recurring urinary tract infections reveals a mildly radiopaque left staghorn calculus (arrows). (*b*) A preoperative intravenous pyelogram was helpful in guiding surgical planning.

requiring transfusion, but several series have shown that utilization of a tract <22 Fr significantly limits this risk. Multiple percutaneous sites may be necessary for complete access to the stone, and have been shown not to increase the risk of transfusion. Long-term follow-up supports percutaneous procedures as being safe, with no significant damage to the pediatric kidney.

Laparoscopy in children has become more widespread and has recently been reported in the management of renal calculi.[86] Patient selection criteria included stones >2.5 cm, with failure of percutaneous renal access. Not only does laparoscopy provide a high stone-free rate but also it enables the repair of concomitant UPJ obstruction. Laparoscopy may also prove helpful in the management of large peripheral caliceal diverticula containing stones, by allowing surgical unroofing with ablation of the diverticular neck and lining. Further experience should better define the role of laparoscopy in the treatment of pediatric stone disease.

Ureteral calculi

Experience with ESWL for stones contained within the ureter has been shown to be effective 54–100% of the time. Retreatment for stones within the ureter is necessary in up to 23% of cases. Patient positioning may need to be modified for distal ureteral stones by placing the child in the prone position. Stones over the bony pelvis are difficult to treat using ESWL because of inadequate visualization and lack of adequate energy delivery.

A review of the literature shows that the stone-free rate after pediatric ureteroscopic lithotripsy is between 77 and 100%.[58,61,87–98] Advances in both endoscopic instrumentation as well as holmium laser lithotripsy have been the major reasons for increased success. In one study, use of holmium laser lithotripsy improved the stone-free rate, compared with pulsed-dye laser and EHL, and was associated with a lower complication rate.[99] In addition, a recent analysis of 65 ureteroscopic lithotripsies in a cohort with a mean age of 7.5 years showed that orifice dilatation is required in only one-third of cases and only one patient developed a ureteral stricture.[100]

One appealing aspect of the ureteroscopic removal of stones is that it offers an immediate stone-free condition at the completion of the procedure. The American Urological Association has issued guidelines to standardize the management of adult patients with stones, and Van Savage et al[95] have published their recommendations for the modification of these guidelines when applying it to the pediatric patient. The ureteroscopic removal of stones contained within the ureter is clearly safe and effective and should be considered the first-line treatment for most children.

The percutaneous removal of ureteral stones is

rarely indicated. It should be considered the primary form of therapy for children who have impacted stones with significant hydroureteronephrosis and urinary tract infection or urosepsis. The antegrade approach allows for prompt decompression of the obstructed collecting system with antegrade ureteroscopic access for subsequent removal. The technique for antegrade ureteroscopy is exactly the same as for the retrograde approach, and has been discussed previously. Flexible rather than mini rigid endoscopy should be utilized for antegrade ureteroscopy to limit potential complications.

Bladder

The term lithotomy was coined in 276 BC by the Greek surgeon Ammonious of Alexandria. It wasn't until the first century AD that the Roman Celsus provided a detailed description of the lithotomy procedure in a young child.[101] Virtually every ancient society has described the surgical removal of bladder calculi. Open cystolithotomy remains part of the practice of pediatric urology to this day (Figure 26.26). In most children, however, the endoscopic removal of such calculi is warranted. Bladder calculi in children are a well-known complication of bladder augmentation when using the large or small intestine.[101,102] They are related to both urinary stasis and mucus production, and occur rarely after gastrocystoplasty. The removal of all stone fragments in these cases is essential to prevent any nidus for stone regrowth, although no difference in stone recurrence is seen after removal of intact calculi or fragmentation techniques.

The cystoscopic removal of bladder calculi is somewhat limited by the caliber of the urethra in young children. All forms of intracorporeal lithotripsy have been proven effective for the management of bladder calculi.[103,104] The most potentially damaging devices to the wall of the augmented bladder include EHL and the holmium laser lithotriptor: it is important that neither of these energy sources come in near or direct contact with the bladder wall. EHL may result in perforation of the augmented bladder if the procedure is performed in a distended bladder or if a stone is wedged against the augmented portion. Other potential complications include gross hematuria from bladder wall irritation, which may necessitate catheterization postoperatively.

Percutaneous removal of bladder calculi has also been demonstrated to be an effective technique.[105–108] This is obviously a more invasive procedure in that it involves a percutaneous suprapubic puncture for direct visualization of the calculi as well as vacuum suction removal. If the urethra is not patent, a second suprapubic puncture is necessary for both visualization and removal of the calculi. This technique appears well suited for stones up to 1 cm in size, or multiple stones <1 cm (Figure 26.27).

The bladder is filled until it is palpable. A small-gauge needle is used to confirm both position and depth in order to percutaneously approach the bladder. A 14-gauge needle is then introduced, which

Figure 26.26 Large bladder calculi such as these require open surgical removal.

Figure 26.27 Small stones in a previously augmented bladder are well suited for either percutaneous or endoscopic removal. Endoscopic removal should not be performed in children who have had previous bladder neck procedures or in the small male urethra. It is imperative that all stone fragments be irrigated free from the bladder in order to help prevent stone recurrence.

allows placement of an 0.038 inch guidewire into the bladder. The tract is then dilated over the wire to a size equal to that of the largest stone in millimeters multiplied by 3 (i.e. an 8 mm stone requires at least a 24 Fr sheath). If intracorporeal lithotripsy is required, either EHL, ultrasonic ballistic, or laser has been proven suitable. The stones and any fragments are then removed using suction tubing attached to a vacuum device. Postoperative bladder drainage is necessary for 5–7 days.

Renal parenchymal imaging in children

27

J Michael Zerin

Increased renal cortical echogenicity and diffuse medical renal diseases

Renal cortical echogenicity in children and adults is normally less than that of the liver and spleen. However, in neonates the renal cortex is usually isoechoic, or even slightly more echogenic than the other solid organs.[1–6] Physiologically, increased renal cortical echogenicity in neonates is attributed to a higher cortical glomerulotubular ratio early in life and usually resolves by 6 months.[5–8] Abnormally increased renal parenchymal echogenicity is the sonographic hallmark of a large and clinically diverse group of glomerular, tubular, and interstitial disorders of the kidneys that are commonly referred to broadly in pediatric imaging as 'medical renal diseases.'[9–15] There is an imprecise relationship between the extent and intensity of the hyperechogenicity and the clinical severity of the renal disease as assessed by functional studies, although the correlation is not usually strong enough to reliably predict outcome. Diffuse renal cortical hyperechogenicity by itself is a non-specific finding requiring correlation with clinical and biochemical findings. The causes of the abnormally echogenic appearance of the cortex in renal parenchymal diseases are not well understood and may not be the same in different disorders. Any process that disrupts the normally well-organized, compact parenchymal architecture is likely to increase the number and reflectivity of the acoustic interfaces in tissue. Alterations in renal perfusion, cellular infiltration, and interstitial edema are all probably important in acute disorders. Fibrosis and histologic disorganization due to nephron disruption probably contribute to the appearance in chronic medical renal disorders.

The extent to which corticomedullary differentiation is affected in diffuse renal parenchymal disease varies widely.[5,11–13,16] In diseases that reduce glomerular perfusion or disrupt glomerular architecture, the pyramids often remain relatively hypoechoic and can even appear somewhat enlarged (Figure 27.1). On the other hand, in tubulointerstitial diseases and diseases that affect the parenchymal echo

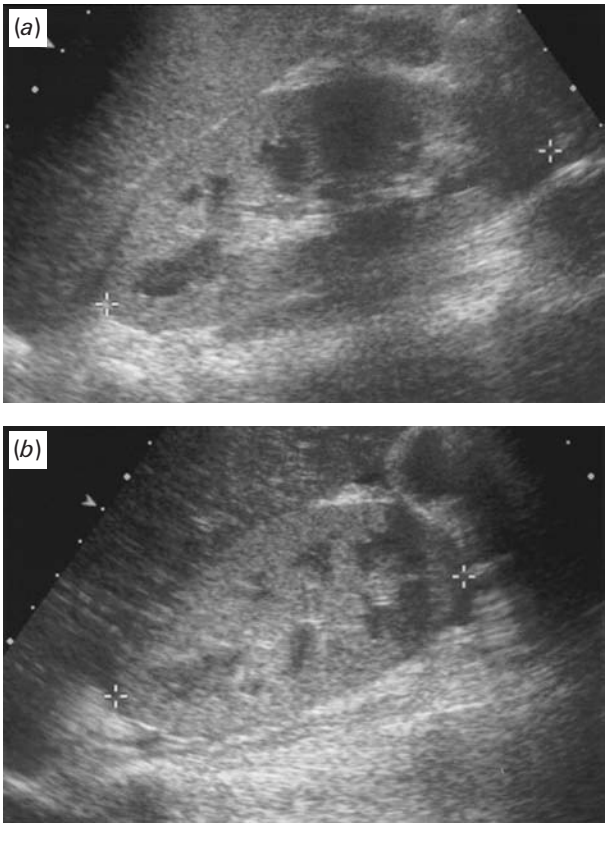

Figure 27.1 A 7-year-old boy with toxic shock syndrome presenting with scalded skin syndrome and acute oliguric renal failure. Ultrasound shows both kidneys are markedly enlarged with diffusely echogenic cortex. However, the pyramids remain hypoechoic and are easily identified. (*a*) Ultrasound: longitudinal view of the right kidney (length 9.3 cm). (*b*) Ultrasound: longitudinal view of the left kidney (length 9.3 cm).

texture more diffusely, both the cortex and the medulla are abnormal and corticomedullary differentiation is more likely to be reduced or absent.

Measurements of the sizes of the kidneys can also be very helpful.[5,11,17] Large, echogenic kidneys usually suggest an acute disorder in which there is edema or cellular infiltration of the renal interstitium. Conversely, small, echogenic kidneys indicate a chronic medical renal condition that is associated with renal atrophy (Figure 27.2). Serial evaluations of the renal sizes and parenchymal echogenicity generally correlate with the clinical course and renal functional assessment, but can also occasionally provide additional prognostic information. In acute medical renal disorders that are associated with generalized enlargement of the kidney, clinical recovery may be associated with return of the renal sizes toward normal, as well as improvement in the echo appearance of the renal cortex. On the other hand, persistence or intensification of the hyperechogenic appearance of the renal cortex is usually accompanied by further clinical and functional deterioration and can indicate a transition to a more chronic phase of the disorder, particularly when the renal sizes are decreasing.

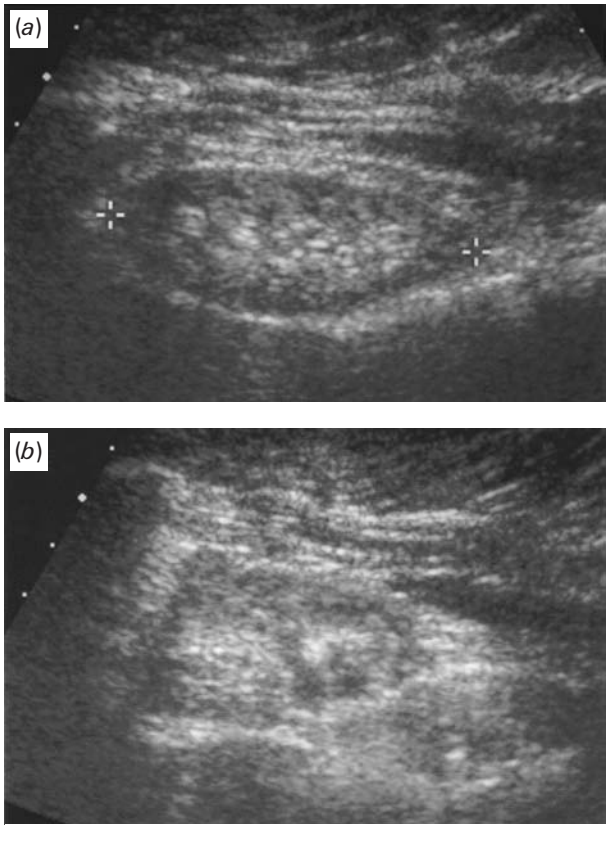

Figure 27.2 A 16-year-old boy with chronic medical renal disease and renal insufficiency on hemodialysis. Ultrasound of the kidneys shows that both kidneys are small with diffusely echogenic parenchyma and no visible corticomedullary differentiation. (*a*) Ultrasound: longitudinal view of the right kidney (length 6.7 cm). (*b*) Ultrasound: longitudinal view of the left kidney (length 6.8 cm).

The appearance of the Doppler waveforms in renal parenchymal diseases generally corresponds to the site of the involvement rather than the specific histopathologic features of the disease.[5,11,15,18] Elevation in the resistive index indicates an increase in the postglomerular resistance. Hence, diseases that increase resistive index include those that cause obstruction at the level of renal veins, tubulointerstitial diseases, obstruction in the collecting system or ureter, and renal compression by disease in the perinephric space. Disorders that primarily cause a reduction in arterial inflow to the kidney and acute glomerular diseases are not typically associated with increased resistive index in the absence of secondary tubulointerstitial injury related to tissue infarction and edema.

Renal infections

Acute pyelonephritis

For several decades, ultrasound (US) has been the most widely used modality for imaging infants and children who have a urinary tract infection.[4,19–29] Inflammatory edema from pyelonephritis causes focal or generalized renal enlargement and bulging renal contours. Dramatic polar enlargement can occasionally mimic an echogenic mass. The walls of the collecting system may also be thickened. Infected parenchyma usually appears hyperechoic, with reduced corticomedullary differentiation (Figure 27.3a). However, severely hypovascular, partially necrotic areas can appear hypoechoic and can be difficult to distinguish from abscess. At power Doppler US, areas of acute pyelonephritis appear as wedge-shaped, hypovascular or avascular zones in the cortex, with the interlobar arteries following abnormally curvilinear courses around the edematous, infected segments.[27,28,30]

Unfortunately, both the sensitivity and specificity of the US findings are limited in acute pyelonephritis. Subtle changes in parenchymal echogenicity or the size and contours of the kidney are often difficult to differentiate prospectively from normal, even when they are easily seen in retrospect.[22,25,31,32] Transient pelvocaliectasis that results from endotoxin, urinary

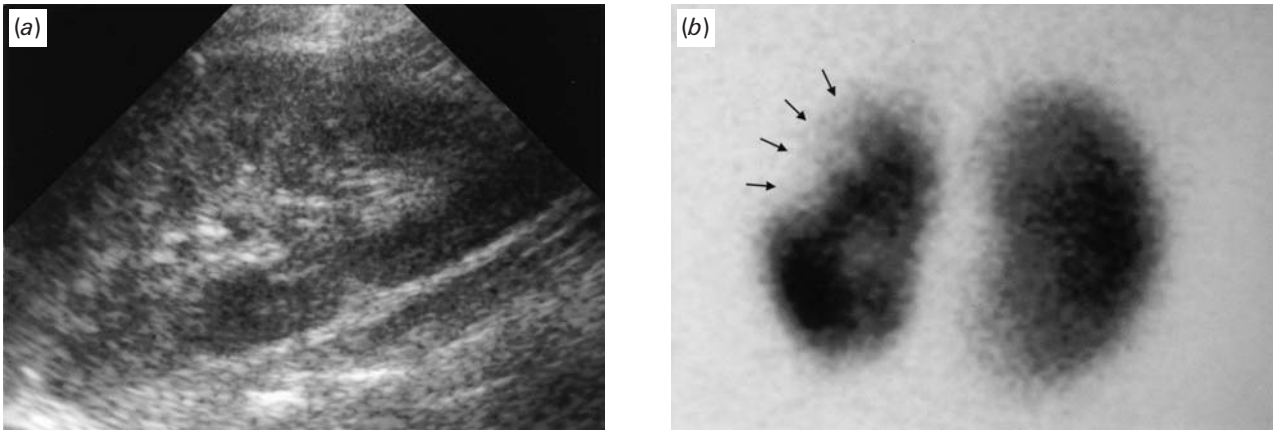

Figure 27.3 A 7-year-old girl with fever and left flank pain due to acute left pyelonephritis. (*a*) Ultrasound: longitudinal view of the left kidney (length 10.3 cm) shows that the upper half of the left kidney is enlarged and echogenic and appears somewhat bulbous compared with the lower pole. (*b*) ^{99m}Tc DMSA renal cortical scintigraphy (posterior view) confirms the presence of a large perfusion defect in the upper half of the left kidney (arrows).

retention, or vesicoureteral reflux (VUR) cannot be readily differentiated from obstructive hydronephrosis. Desquamated cellular and crystalline material in chronically obstructed, uninfected systems similarly cannot be reliably distinguished sonographically from purulent urine. Although power Doppler US is an excellent adjunct to the conventional gray-scale examination, it is less sensitive than renal cortical scintigraphy, computed tomography (CT), or magnetic resonance imaging (MRI).

At ^{99m}Tc DMSA (technetium 99m dimercaptosuccinic acid) renal cortical scintigraphy, acute pyelonephritis appears as wedge-shaped or triangular areas of diminished cortical uptake[25,27,33–36] (Figure 27.3b). Most defects occur in the renal poles and the adjacent renal contour often bulges outwardly. Rarely, diffuse pyelonephritis produces a globally enlarged, poorly functioning kidney. Acute defects resolve within 4–6 months after treatment, in the absence of scar formation. Dynamic planar diuretic ^{99m}Tc MAG3 (technetium 99m mercaptoacetyltriglycine) renal scintigraphy has also been used to diagnose acute pyelonephritis.[37,38] Functional defects caused by pyelonephritis show decreased early uptake and fill in slowly on static images, with prolonged late retention of activity. Fixed functional defects that persist on all phases can represent either acute pyelonephritis or scar.

At contrast-enhanced CT, acute pyelonephritis appears as segmental areas of decreased or striated parenchymal enhancement, with edematous, convex, rounded margins, most commonly in the renal poles[25,29,30,36,39,40] (Figure 27.4). The abnormal appearance can persist for several months before resolving or progressing to scar formation. Acute pyelonephritis is more difficult to detect on non-

Figure 27.4 An 18-month-old girl with bilateral acute multifocal pyelonephritis, presenting with high fever and febrile seizure. Contrast-enhanced CT shows multiple wedge-shaped, low-attenuation, non-enhancing lesions in both kidneys.

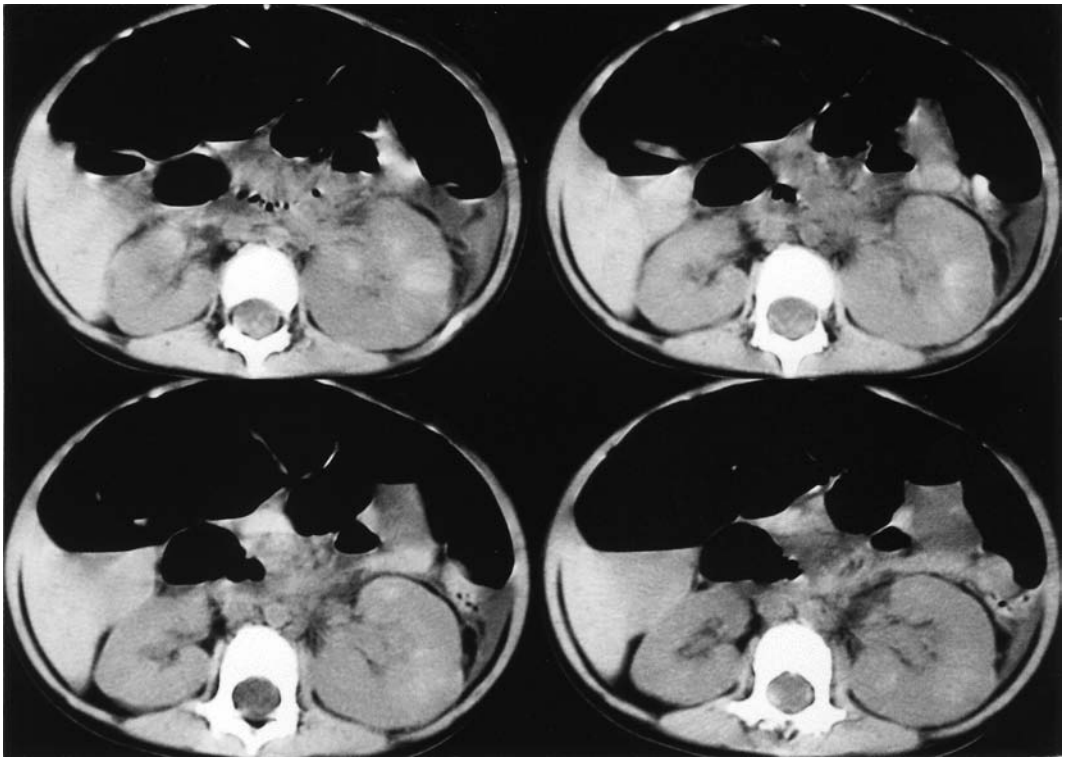

Figure 27.5 A 3-year-old girl with acute hemorrhagic pyelonephritis presenting with fever, gross hematuria, and *E. coli* bacteremia. Intravenous contrast material was not given for CT because of acute renal insufficiency requiring peritoneal dialysis. Non-enhanced CT shows that her left kidney is enlarged, with multiple slightly higher attenuation areas scattered throughout the parenchyma. Several similar, more subtle lesions are also present in the right kidney.

enhanced CT because the infected areas are isodense or only slightly hypodense in comparison with normal parenchyma. Increased attenuation within an area of acute pyelonephritis on non-enhanced CT may suggest parenchymal hemorrhage (Figure 27.5).

On postcontrast, fast spin-echo T2 and inversion recovery MRI sequences, gadolinium-related T1 and T2 shortening causes normally enhancing parenchyma to have markedly reduced signal intensity, whereas non-enhancing areas of acute pyelonephritis remain very bright.[29,35,36,40–43] Marked hyperintensity is also seen in both pyelonephritis and renal abscess on diffusion-weighted MRI.[44–46] Restricted diffusion in pyelonephritis is primarily due to cytotoxic edema, although intratubular inspissation of inflammatory cells is also probably important.

Published studies comparing these modalities[30,33,35,36] show no significant differences between DMSA, CT, and MRI, either in the diagnosis of pyelonephritis (sensitivity >90%) or in the localization of lesions. However, power Doppler US is less sensitive. Interobserver agreement is better for both CT and MRI than for DMSA. The ability to reliably differentiate scars from acute infection in the absence of a previous study is another important benefit of both CT and MRI. MRI also offers the advantages of multiplanar imaging and lack of ionizing radiation.

Fungal pyelonephritis

Fungal pyelonephritis is usually associated with fungal sepsis and occurs principally in neonates with indwelling central venous catheters and in children who are immunocompromised.[42,45–48] Hyperalimentation is another important risk factor. *Candida albicans* is the most common organism. In neonates with diffuse renal infection with *Candida*, US shows renal enlargement and diffuse parenchymal hyperechogenicity. Fungus balls (bezoars) appear as nonshadowing hyperechoic masses within the collecting system and can cause obstruction. Focal areas of fungal pyelonephritis appear hypoechoic and have low attenuation at CT[42,46,49,50] (Figure 27.6). Fungal abscesses have imaging features similar to those of bacterial abscesses.

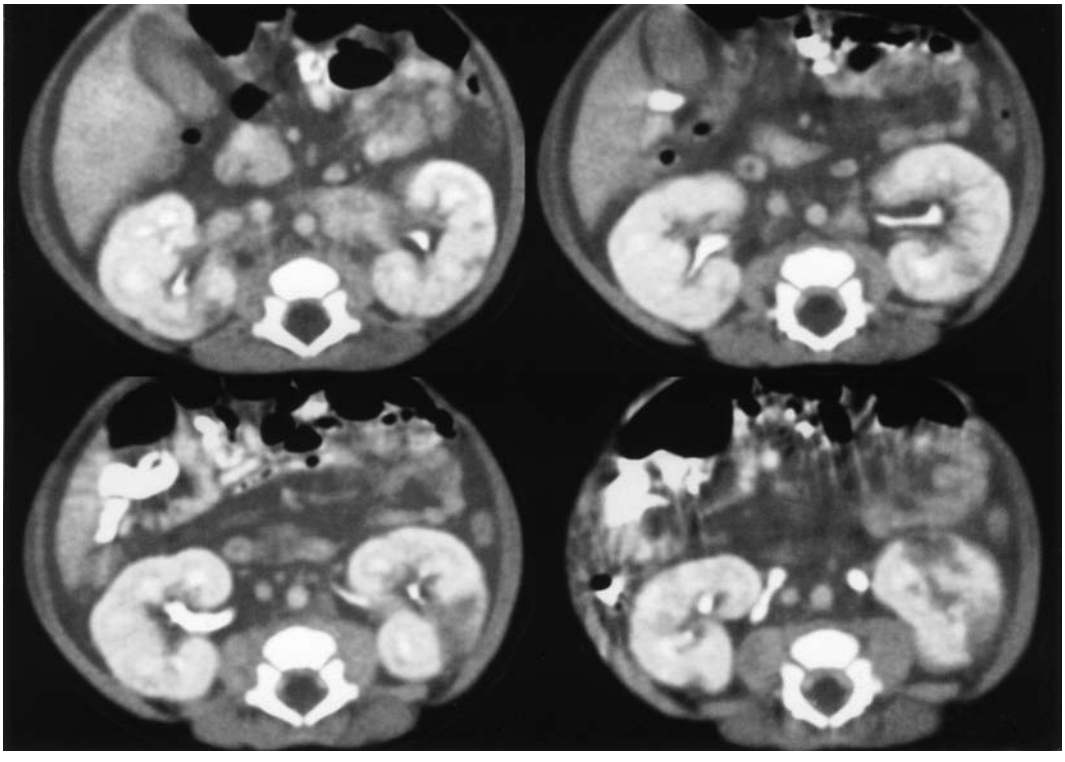

Figure 27.6 A 2-week-old boy with *Candida albicans* sepsis and bilateral fungal pyelonephritis. Contrast-enhanced CT shows both kidneys are enlarged and contain multiple scattered, peripheral, low-attenuation, non-enhancing parenchymal lesions.

Complications of acute pyelonephritis

At US, a renal abscess appears as a round, hypoechoic or anechoic, fluid-filled intraparenchymal mass with a thick, irregular wall.[9,10,25] Abscesses can be unilocular or multilocular and usually contain layering, echogenic debris. The appearance of adjacent parenchyma is usually consistent with acute pyelonephritis. Large perinephric abscesses are readily visualized with US. However, contrast-enhanced CT provides superior definition of both the intra- and extrarenal extent of the infection[39,42,46,51,52] (Figure 27.7). On a postcontrast CT, a renal abscess appears as a hypodense, cystic mass with an irregularly thickened, enhancing wall. Non-enhanced CT is generally less satisfactory. MRI is an excellent alternative to CT in patients in whom iodinated contrast media is contraindicated.

Pyonephrosis represents acute bacterial infection in a kidney with a dilated, obstructed collecting system. The sonographic appearance of a dilated collecting system filled with urine and floating or layering echogenic debris is suggestive of pyonephrosis.[25,42,46,51,52,53] Areas of pyelonephritis are often also evident and the kidney may be enlarged. Air bubbles in the collecting system appear as irregular, brightly echogenic, shadowing foci and usually float on top of the urine, a feature that distinguishes them from calculi, which tend to sink to more dependent locations. Hydronephrosis, with thickening and enhancement of the collecting system walls, is readily demonstrated at CT, as are associated areas of pyelonephritis. Calculi and air in the collecting system are also visible at CT. Although US provides superior definition of particulate debris in the collecting system, care should be taken not to mistake transient hydronephrosis that results from endotoxin-induced atony, urinary retention, or reflux for pyonephrosis. Debris may be present in children with uncomplicated pyelonephritis who have a non-obstructed system. Similarly, air that is introduced into the bladder during catheterization can also reach the collecting system in children with reflux. Mild dilatation is usually of little concern, particularly if the patient is otherwise healthy and responds rapidly to antibiotics. When the dilatation is more severe and a large amount of echogenic debris or air is present ('pseudo-pyonephrosis'), differentiation from pyonephrosis can be difficult.[25]

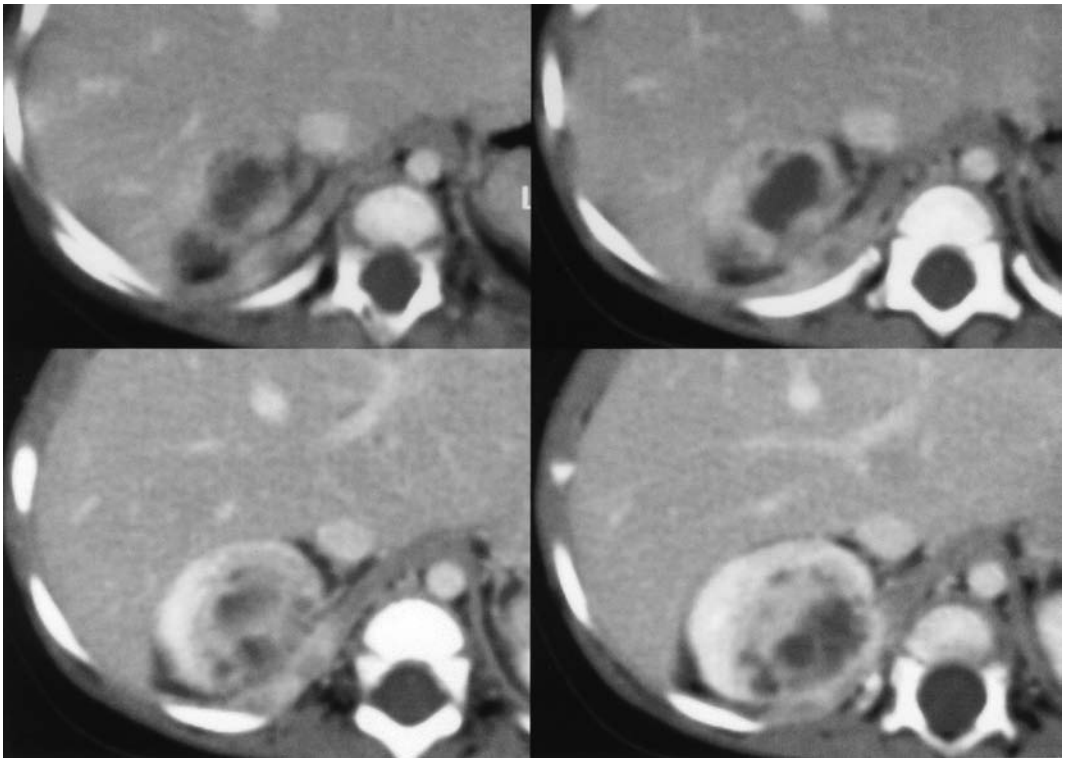

Figure 27.7 A 9-month-old boy with right acute pyelonephritis and intrarenal abscess. Contrast-enhanced CT shows a complex large-area abnormal enhancement with necrosis in the upper pole of the right kidney.

Xanthogranulomatous pyelonephritis is a rare form of chronic bacterial renal infection, usually caused by either *Escherichia coli* or *Proteus* spp., in which granulomatous infiltration of the kidney by lipid-laden macrophages leads to extensive parenchymal destruction.[25,42,54–57] Nephrolithiasis and chronic upper urinary tract obstruction are frequently present. The US appearance in diffuse xanthogranulomatous pyelonephritis is of a markedly enlarged, echogenic kidney in which the normal renal architecture is obliterated. Multiple hypoechoic, mass-like areas of parenchymal necrosis are visible throughout the kidney. Calculi are common, although the collecting system is usually not dilated. At postcontrast CT, the affected kidney is non-functioning and the parenchyma appears low in attenuation due to necrosis and infiltration by the lipid-laden macrophages ('foamy histiocytes'). One or more calculi are usually present. Perinephric and paranephric extension is better demonstrated at CT than US. Focal xanthogranulomatous pyelonephritis is quite rare and presents as a large, inflammatory, renal mass. The mass is hypoechoic at US and hypodense and nonenhancing at CT. Visualization of a calculus within the mass or in an adjacent calyx can be an important clue to the diagnosis.

Chronic atrophic pyelonephritis (reflux nephropathy)

Cortical scars and parenchymal atrophy in chronic pyelonephritis result from recurrent episodes of acute pyelonephritis.[23,27,29,34,58] Cortical scars are most common in the renal poles and typically become visible 4–6 months following infection. At excretory urography, cortical scarring appears as a deformed ('clubbed') calyx beneath an area of parenchymal thinning. The indentation in the surface of the kidney immediately overlying the affected calyx becomes more conspicuous over time as a result of fibrous retraction within the scar itself and continued growth of adjacent normal parenchyma. Although excretory urography was used extensively in the past, it has been entirely replaced by US for evaluating children with pyelonephritis.[4,19,20,21,23,27] The US findings of chronic pyelonephritis include a small poorly growing kidney with focal or diffuse cortical atrophy. Dilated, blunted calices are often present. Whereas larger cortical scars are usually easily identified, smaller scars are often not seen at US. Careful serial evaluation of renal measurements is critical, since poor renal growth and generalized parenchymal thinning may be present, even when focal scarring is not visible. In advanced cases, the kidney will appear

small and irregular with diffusely echogenic parenchyma, indistinguishable from other forms of end-stage chronic medical renal disease.

Persistent fetal lobation (lobulation) and junctional parenchymal defect are two common, normal developmental variations in renal shape that should not be mistaken for cortical scarring at US.[5,6,29,59] Fetal lobation produces a smoothly undulating renal outline with evenly distributed superficial clefts between the fetal renal lobes. The indentations lie between the pyramids rather than over them, as in cortical scarring, and the adjacent calices are not dilated. Junctional parenchymal defect is a triangular, echogenic, cortical indentation along the anterolateral aspect of the junction of the mid and upper thirds of the kidney.[5,6,29,60] The defect extends inferomedially into the renal sinus and represents the anterior site of fusion of the superior and inferior renunculi.

The appearance of chronic pyelonephritis at ^{99m}Tc DMSA depends on the number, size, stage of maturation, and location of the scars.[27,29,34,61] Mature scars appear as sharply defined, wedge-shaped cortical defects. Renal volume is reduced and the renal contour is flattened due to fibrous retraction and loss of parenchymal substance. Cortical scars tend to appear more sharply defined than defects caused by acute pyelonephritis. However, the most reliable way to distinguish between acute and chronic cortical defects is to compare sequential examinations. Careful correlation with the clinical setting and with other imaging modalities, such as US, is also essential to assure that the defects are the result of pyelonephritis or scarring rather than of other lesions such as cysts, caliceal diverticula, or masses.

At MRI, chronic pyelonephritic scars appear as irregular cortical indentations that do not change in signal intensity between pre- and postcontrast inversion recovery sequences.[42,46,62,63] As scars mature, fibrous retraction leads to progressive loss of parenchymal volume. Although CT can also provide excellent anatomic and functional information in children with chronic pyelonephritis, this modality is rarely used for this application.

Renal vascular diseases

Renal vein thrombosis

Renal vein thrombosis presents with gross hematuria, hypertension, and an enlarged, palpable kidney.[5,11,42,64,65] Premature infants, infants of diabetic mothers, and neonates and infants with severe dehydration, hypotension, sepsis, or asphyxia are at greatest risk. Renal vein thrombosis also occurs in children with coagulopathies. Renal vein thrombosis is usually unilateral and the affected kidney functions poorly. Bilateral thrombosis causes severe renal insufficiency. In neonates and infants, thrombus formation begins in smaller intrarenal veins and the main renal vein and inferior vena cava are often patent. In neonates with adrenal hemorrhage, extension of thrombus into the kidney from the adrenal vein can lead to ipsilateral renal vein thrombosis. This is more common on the left, since the left adrenal vein drains directly into the left renal vein.

Renal vein thrombosis is usually diagnosed at US.[5,6,11,66–68] In the acute phase, the kidney is globally enlarged, and the parenchyma is diffusely echogenic with poor corticomedullary differentiation. Larger thrombi within interlobar and intralobular renal veins appear as linear, echogenic bands radiating peripherally between the renal lobes. Adjacent perivascular hemorrhage probably also contributes to this appearance. Thrombus can also be visible in the main renal vein and inferior vena cava. Even when the main renal vein is patent, the amplitude of flow is reduced at Doppler US. More importantly, renal artery Doppler US shows reduced or even retrograde flow during diastole, with markedly increased resistive index.[18] MAG3 renal scintigraphy shows a globally enlarged kidney, with markedly reduced or absent uptake and no excretion. With recovery, the affected kidney decreases in size as the edema recedes and there is variable restoration of function. Serial US examinations are required to document stabilization of the renal size and resumption of a normal rate of growth. Persistent cortical hyperechogenicity and diminished corticomedullary differentiation indicate parenchymal atrophy and are associated with poor functional recovery. With severe parenchymal infarction and parenchymal necrosis, severe atrophy and cyst formation can result in a small, echogenic, poorly functioning kidney.[5,6,11,42,66,67] In the chronic phase, punctate, linear, or branching calcifications can appear within the thrombosed intrarenal veins.[69,70] The presence of linear and punctate renal calcifications in a neonate with a small echogenic kidney is strongly suggestive of prenatal renal vein thrombosis.[71]

CT and MRI are rarely performed in children with renal vein thrombosis, since the diagnosis is readily established at US and MAG3 renal scintigraphy.[42,64,68] During the acute phase, the affected kidney is enlarged and edematous. Perfusion is diminished with

inhomogeneous parenchymal attenuation and markedly reduced or no enhancement. Parenchymal infarction and hemorrhage are common. Associated adrenal hemorrhage and thrombosis of the inferior vena cava are also readily visualized. In the chronic phase, parenchymal atrophy ensues, with calcification of the residual thrombus in the renal veins and inferior vena cava.

Renal artery thrombosis

Non-traumatic renal artery thrombosis occurs primarily following umbilical or femoral artery catheterization, in infants of diabetic mothers, and in infants and children with sepsis, severe dehydration or hemoconcentration, coagulopathy, or vasculitis. The extent of parenchymal injury depends on the size of the occluded vessel. Complete occlusion of the main renal artery results in global renal infarction.[11,72,73] During the acute phase, the kidney may initially remain normal in size or even be slightly small and the cortex becomes hyperechoic, although the pyramids remain hypoechoic. Doppler imaging reveals reduced or absent flow in the main and segmental renal arteries with normal or low resistive index. Visualization of the echogenic intraluminal-filling defect representing the thrombus within the main renal artery is diagnostic. As parenchymal infarction and hemorrhage develop, the kidney swells and becomes increasingly echogenic and inhomogeneous, ultimately leading to complete disruption of the normal corticomedullary architecture. Functional evaluations such as renal scintigraphy show no uptake or excretion by the affected kidney. As in renal vein thrombosis, CT and MRI are rarely performed in neonates and infants with renal artery thrombosis. The anatomic and functional outcomes depend on the extent of parenchymal infarction and the timing and degree of revascularization. Chronic ischemia results in an atrophic, poorly or non-functioning echogenic kidney that is small with smooth, reniform contours. Small parenchymal calcifications and cysts can also be seen.

Segmental renal artery occlusion causes a wedge-shaped, avascular segmental defect with its apex at the renal hilum and its base at the renal capsule.[11,73] Doppler imaging can confirm the absence of flow in the infarct, although scar formation can be difficult to differentiate from that seen in chronic pyelonephritis. Intravascular sonographic contrast agents may improve visualization of cortical perfusion defects with power Doppler US, although this remains to be applied in clinical practice.[74,75]

Hemolytic uremic syndrome

Hemolytic uremic syndrome is a bacterial toxin-mediated vasculitis that is manifested clinically by acute renal failure, microangiopathic hemolytic anemia, fever, and thrombocytopenia. The disease primarily affects children <5 years of age and is frequently preceded by an episode of gastroenteritis associated with severe abdominal cramping and bloody diarrhea. Intimal inflammation with thrombosis of small intrarenal arteries and capillaries leads to acute renal failure with severe oliguria or anuria and hypertension. Spontaneous recovery usually occurs within 3–4 weeks, although dialysis is often necessary during the acute phase.

During the acute phase in hemolytic uremic syndrome, the kidneys are normal in size or slightly enlarged. The renal cortex is diffusely hyperechoic and the medullary pyramids are hypoechoic.[11,76,77] At Doppler US, the resistive index is elevated, with markedly reduced or absent forward diastolic flow in the renal arteries. Occasionally, flow can even be reversed during diastole, as in renal vein thrombosis. Normalization of the arterial waveform may precede the onset of diuresis during the recovery phase.[78] Cortical echogenicity also returns to normal in most children who experience complete recovery of renal function.

Nephrocalcinosis and other causes of renal medullary hyperechogenicity

Medullary nephrocalcinosis is the most common cause of renal medullary hyperechogenicity in infants and children.[11,42,79–81] Hypercalciuria, increased urinary phosphate excretion, and hypercalcemia are important predisposing factors. Dystrophic renal calcification can also form secondary to severe parenchymal injury from trauma, infection, or infarction.

Sonographically, nephrocalcinosis shows a characteristic periphery-to-center progression, with increased echogenicity first developing along the margins of the pyramids[11,42,82–84] (Figure 27.8). Over time, this peripheral echogenic rim gradually thickens, eventually filling in the centers of the pyramids. In the most severe cases, the pyramids are diffusely, intensely echogenic with posterior acoustic shadowing. Aggregates of extracellular calcium near the papillary tips (Randall's plaques) can perforate the caliceal epithelium, leading to extrusion of calculi into the collecting system (Anderson–Randall–Carr phenome-

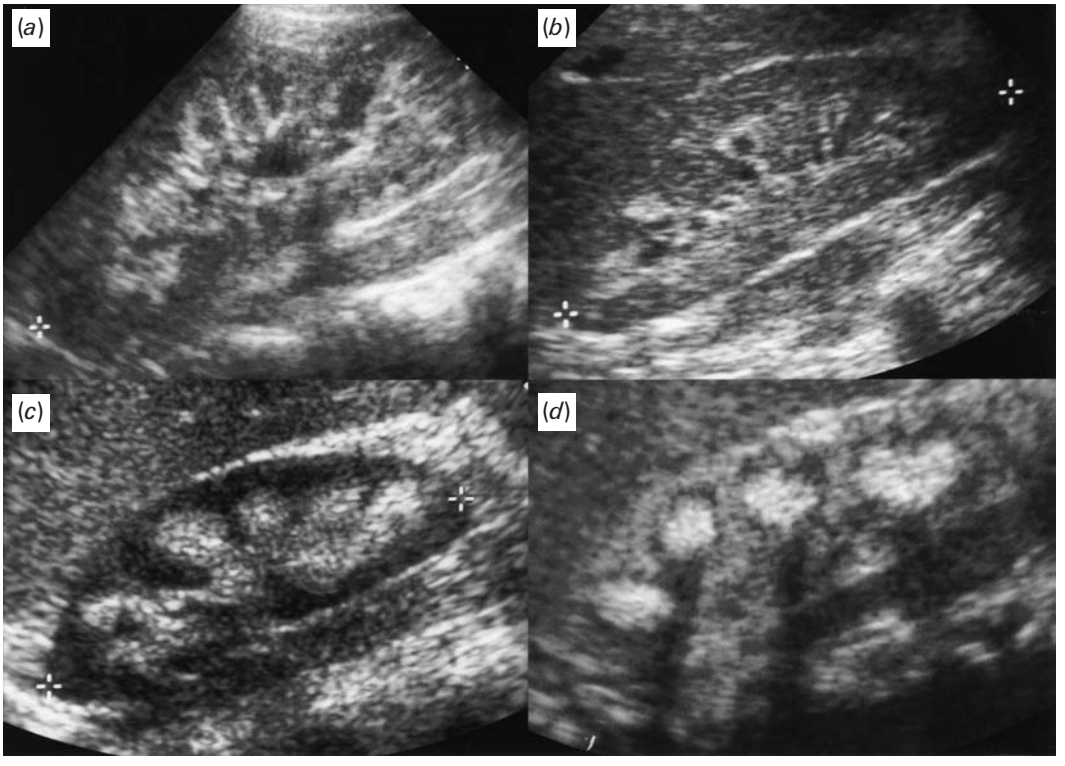

Figure 27.8 Sonographic patterns of medullary hyperechogenicity in nephrocalcinosis. (*a*) Longitudinal view of the left kidney in a 3-year-old girl with Williams syndrome shows thin, peripheral hyperechoic linear bands outlining the pyramids with the centers remaining hypoechoic. The cortex appears normal. (*b*) Longitudinal view of the right kidney in a 14-year-old boy with familial hypophosphatemic rickets shows thicker peripheral echogenic margins of the pyramids. Some pyramids appear almost uniformly hyperechoic. The cortex appears normal. (*c*) Longitudinal view of the right kidney in a 7-year-old boy with distal renal tubular acidosis shows diffusely and nearly homogeneously hyperechoic medullary pyramids. There is no posterior acoustic shadowing and the cortex appears normal. (*d*) Longitudinal view of the right kidney in a 7-week-old girl with severe idiopathic hypercalcemia shows very intense, diffuse medullary hyperechogenicity with posterior acoustic shadowing. The cortex is also thin and echogenic, consistent with cortical nephrocalcinosis.

non). Even in cases with marked medullary hyperechogenicity at US and increased medullary attenuation at non-enhanced CT, the calcification is not always visible on abdominal radiographs. Cortical calcification usually occurs only in the presence of advanced medullary nephrocalcinosis and is associated with marked hypercalcemia or severe generalized parenchymal injury, or both. Cortical nephrocalcinosis is manifested at sonography by generalized increase in cortical echogenicity, cortical acoustic shadowing, loss of the corticomedullary differentiation, and atrophy.

Renal medullary hyperechogenicity is also seen in a number of uncommon storage diseases, including glycogen storage disease, Lesch–Nyhan syndrome, and Wilson's disease, among others.[79,80,85–87] Both hypercalciuria and microscopic evidence of increased medullary calcium deposition have been reported in patients with these disorders. Hyperuricemia might also contribute in some patients, as it is known to produce hyperechoic pyramids in adults with gout and in children with leukemia. In some subtypes of glycogen storage disease, the kidneys are enlarged and become increasingly echogenic as a result of tubular and interstitial deposition of calcium, uric acid, and glycogen. The liver and spleen are also enlarged and echogenic. In Lesch–Nyhan syndrome, renal function is usually normal during childhood although the kidneys are small. Increased medullary echogenicity can be punctate or diffuse and is typically progressive and unaffected by therapy. Both nephrocalcinosis and renal calculi can develop.

Tamm–Horsfall proteinuria and other inspissation syndromes

Transient medullary hyperechogenicity as a result of intratubular inspissation of Tamm–Horsfall protein

has been reported in 3–5% of otherwise healthy term neonates during the first week of life.[88,89] At US, the pyramids can appear diffusely speckled or the abnormality can appear as a splotchy hyperechoic focus involving the inner third of the pyramid, extending outward from the papillary tip. The abnormality can be unilateral or bilateral and is visible shortly after birth. Despite the fact that the deposits can be quite conspicuous at US, they are not visible at nonenhanced CT. Physiologically, decreased tubular flow during the first days of postnatal life is thought to be important. Tamm–Horsfall protein is known to precipitate and form intratubular aggregates when present in larger than normal quantity. Urinary excretion of Tamm–Horsfall protein is normally higher at birth and declines during the first week. Some authors have reported a temporal relationship between the disappearance of the hyperechogenicity and the establishment of a consistent pattern of micturition toward the end of the first week of life.

Similar sonographic appearances have been reported in children and adults with oliguric renal failure and persistently increased urinary Tamm–Horsfall excretion.[11] Medullary hyperechogenicity is also observed in patients with intratubular deposition of other large macromolecules, such as in rhabdomyolysis, myoglobinuria, toxic shock syndrome, and in children with leukemia and tumor lysis syndrome. The resistive index is usually increased at Doppler US examination and renal dysfunction is common. The reversibility of the US findings depends on re-establishment of a normal urine flow rate.

Renal tumors

Wilms' tumor

Wilms' tumor is a malignant neoplasm that arises from primitive, embryonal renal tissue and is the most common primary, solid, neoplasm in the pediatric abdomen, accounting for 95% of all malignant genitourinary neoplasms in children.[42,90,91] Most children with Wilms' tumor present between 1 and 4 years of age. Because Wilms' tumors grow rapidly, they are usually very large at diagnosis and present as a palpable abdominal mass. Hematuria, fever, abdominal pain, and hypertension are also common. Children with hemihypertrophy, sporadic aniridia, Beckwith–Wiedemann syndrome, Denys–Drash syndrome, and Perlman syndrome are predisposed to developing Wilms' tumor, but represent less than 5% of all cases.[92,93]

Wilms' tumor usually presents as a solitary renal mass and can occur anywhere in the kidney.[90–92,94,95] Multiple synchronous Wilms' tumors are present in 5% of patients at diagnosis and can be unilateral or bilateral (Figure 27.9). Metachronous contralateral tumors can also appear even many years after the nephrectomy for the original mass. The mass itself is surrounded by a well-defined pseudocapsule comprising tissue that has been compressed along the advancing surface of the enlarging mass. Histologically, Wilms' tumors are classified as either 'favorable' or anaplastic. Wilms' tumors with favorable histology account for more than 90% of cases. Children with anaplastic Wilms' tumors tend to be older and their tumors display a greater tendency to invade adjacent structures, as well as a higher frequency of distant metastases. Hematogenous metastasis is most common to the lungs, liver, and brain. Skeletal metastases are rare. Lymphatic spread to renal hilar and para-aortic lymph nodes can also occur. Intravascular extension into the renal vein and inferior vena cava occurs in 4% of children and in 1% the tumor thrombus propagates into the right atrium.

Ultrasound is the usually the first imaging study that is performed in an infant or young child who presents with a palpable abdominal mass.[5,11,42] At US, Wilms' tumor appears as a solid, intrarenal mass. The mass is often very large (>10 cm) and is usually primarily solid and hyperechoic. Cystic areas of necrosis

Figure 27.9 A 3-year-old girl with bilateral synchronous Wilms' tumors and right nephroblastomatosis. At contrast-enhanced CT, the left kidney is almost entirely replaced by a large, partially necrotic mass (Wilms' tumor) and there is a somewhat smaller mass (Wilms' tumor) distending the right renal sinus. Numerous tiny, low-attenuation perilobar nephrogenic rests (arrows) are visible in the residual enhancing right kidney.

and hemorrhage can be very extensive. However, primarily cystic Wilms' tumors are rare. At nonenhanced CT, Wilms' tumor presents as a low-attenuation, solid renal mass.[42,96] On postcontrast scans, the tumor generally appears more inhomogeneous, with variable enhancement of the solid components and no enhancement in cystic areas of hemorrhage and necrosis (Figures 27.9 and 27.10). Calcification is visible in less than 10% of cases. Wilms' tumors containing small amounts of fat have been reported rarely.[97] At MRI, the mass appears moderately inhomogeneous with relatively low signal intensity on T1-weighted sequences and has a bright signal on T2-weighted sequences.[42,98–100] Solid areas within the tumor enhance on postgadolinium sequences, although less than normal renal cortex. When present, calcification appears as very low signal foci, and is much less conspicuous at MRI than at either CT or US.[100,101] CT and MRI generally provide similar information regarding local tumor extent and regional adenopathy and are both superior to US for tumor staging.[91,102] In selected cases, direct multiplanar imaging with MRI can provide more detailed information, such as when direct invasion of adjacent structures is difficult to assess at CT. On all three modalities the contralateral kidney should be evaluated carefully for tumor or nephroblastomatosis. Although some clinicians have challenged routine intraoperative inspection and palpation of the contralateral kidney, this is still a widely accepted surgical practice, even when preoperative imaging studies show no contralateral renal abnormality.[95] Because of the propensity of Wilms' tumor to grow into the renal vein and inferior vena cava, these structures should be carefully evaluated.

Figure 27.10 A 2-year-old girl with large left Wilms' tumor with extension into the left renal vein and inferior vena cava. Contrast-enhanced CT shows a large non-enhancing, solid left renal mass containing multiple small areas of necrosis and hemorrhage. Low-attenuation soft tissue is visible distending the left renal vein and inferior vena cava (arrow).

Identification of the superior extent of the thrombus is critical for presurgical planning[91,103,104] (see Figure 27.10). Gross intracaval tumor extension is usually readily visualized at Doppler US or with CT or MRI. However, both CT and MRI generally provide more detailed visualization of the vascular anatomy and can more readily demonstrate tumor extension into the adrenal or gonadal veins that may not be visible at US. Because the right renal vein is very short, sonographic evaluation of intravascular extension can also be more challenging in tumors that arise in the right kidney, particularly when they are very large. Large right renal tumors also often compress the inferior vena cava, even when there is no intravascular tumor. Congenital variations in the left renal vein (either retroaortic or circumaortic) can pose a challenge in patients with left renal tumors.

Ultrasound is generally used for postnephrectomy surveillance of both the nephrectomy bed and the contralateral kidney in children with Wilms' tumor.[11,42,105] Power Doppler US can aid in identifying smaller intrarenal masses that might not be as conspicuous on gray-scale imaging alone. Careful comparison with previous studies is critical and any unexplained change in the renal contour or focal enlargement of one portion of the kidney should be viewed with suspicion even when there is no clearly definable mass. CT or MRI should be performed when there is any question of a recurrent or contralateral mass.

Nephroblastomatosis

Nephroblastomatosis is the persistence of non-functioning, primitive, nephrogenic blastema in the kidney after birth.[94] Perilobar nephrogenic rests are positioned at the boundaries between the renal lobes and are more common than intralobar rests, which are located deep within the cortex or medulla. Panlobar nephroblastomatosis is a rare condition in which both kidneys are nearly entirely replaced by nephrogenic rest tissue (Figure 27.11). The clinical importance of nephroblastomatosis lies in the potential for malignant transformation of nephrogenic rests into Wilms' tumor.[94,106,107] Neoplastic transformation is more common with intralobar rests, although malignancy can develop within perilobar rests.

Figure 27.11 A 14-month-old boy with panlobar nephroblastomatosis, presenting with a markedly distended abdomen and bilateral palpable flank masses. Contrast-enhanced CT shows the kidneys are almost completely replaced by multiple low-attenuation, nonenhancing, solid masses. Residual compressed strands of functioning renal parenchyma are visible between the masses.

Macroscopic nephrogenic rests usually appear as hypoechoic solid masses at US.[107–110] At CT, nephrogenic rests have low attenuation and do not enhance (see Figure 27.10). CT is more sensitive than US in detecting nephroblastomatosis, although some lesions that are visible at US are not seen at CT and vice versa. Sclerosed perilobar rests can produce an irregularly flattened renal contour mimicking cortical scars from reflux nephropathy, whereas involuted intralobar rests can simulate renal cysts or caliceal diverticula. At MRI, nephrogenic rests do not enhance and appear homogeneously hypointense compared with cortex and isointense compared with the medulla on both T1- and T2-weighted sequences.

In children with Wilms' tumor, nephrogenic rests that are identified on prenephrectomy imaging studies should be carefully followed on subsequent examinations. Although some nephrogenic rests can be identified intraoperatively at the time of nephrectomy by inspection and palpation of the kidneys, many perilobar rests and most intralobar rests are not detectable in this fashion, including some that are identifiable at CT or MRI.[95] Microscopic nephrogenic rests are not detectable with any current imaging modality.

Patients who have syndromes that are associated with nephroblastomatosis and Wilms' tumor should have their kidneys screened periodically with US during infancy and early childhood.[90,92,93] Although the optimal frequency and duration of such US surveillance has not been well established, we follow patients every 3–6 months through infancy while progressively lengthening the interval between studies as the child gets older.[42,93,111] Just as is the case when following children with previous Wilms' tumor, careful comparison of the current examination with previous studies is critical and any unexplained change in the renal contour or focal or asymmetric enlargement should be viewed with suspicion even when there is no clearly definable mass or definite change in echo texture. Power Doppler US can also help to identify smaller intrarenal masses that might not be as conspicuous on gray-scale imaging alone. Whenever there is a question of a mass, CT or MRI should be performed without hesitation.

Clear cell sarcoma

Once thought to be a variant of Wilms' tumor, clear cell sarcoma accounts for 5% of primary pediatric renal tumors.[112–115] Children with clear cell sarcoma tend to be slightly older than those with Wilms' tumor and have a much poorer prognosis. The predilection for skeletal metastases in clear cell sarcoma also differentiates it from Wilms' tumor, in which skeletal metastases are rare. Clear cell sarcoma is also not associated with nephroblastomatosis. Ultrasound, CT, and MRI all demonstrate a predominantly solid, although usually complex renal mass with imaging characteristics that are usually indistinguishable from Wilms' tumor.[115] Well-defined cystic areas of necrosis and hemorrhage are common. Skeletal metastases can either be present at the time of initial diagnosis or can appear later and are usually osteolytic, although osteoblastic metastases also occur.[114] Both hot and cold defects can be seen on bone scan.

Malignant rhabdoid tumor

Malignant rhabdoid tumor is a very rare, aggressive, primary malignant pediatric renal neoplasm that frequently presents during the first year of life.[116] Malignant rhabdoid tumor is associated in up to half of patients with a histopathologically diverse group of primary central nervous system tumors, including primitive neuroectodermal tumor, ependymoma, and astrocytoma.[117] These tumors can be present when the renal mass is first detected or can appear later. At ultrasound, CT, and MRI, malignant rhabdoid tumor presents as a large, aggressive, infiltrating, solid renal mass.[118] The mass often arises centrally within or

adjacent to the renal hilum and invades and compresses surrounding parenchyma as it enlarges. Linear calcifications are common. In some cases, the calcifications appear to outline distinct tumor lobules. Rapid enlargement of the mass can lead to necrosis and hemorrhage. Peritumoral hemorrhage can also occur, resulting in characteristic crescent-shaped fluid collections at the periphery of the mass. Because of the tumor's frequent association with both primary and metastatic neoplasms of the central nervous system, CT or MRI of the brain should be performed whenever the diagnosis of malignant rhabdoid tumor is suspected.

Renal cell carcinoma

The mean age at presentation in children with renal cell carcinoma is 11–12 years, although it has been reported as early as 6 months of age. Patients usually present with painless gross hematuria, abdominal pain, or a palpable mass. The histopathologic and imaging features of renal cell carcinoma in children are similar to adults. The tumor usually appears hyperechoic at US and hyperdense at CT, with variable tumor enhancement[119,120] (Figure 27.12). Necrosis and hemorrhage are common. Calcification is more common than in Wilms' tumor. Children with renal cell carcinoma have a relatively good prognosis if the entire tumor can be removed. However, if the primary resection is incomplete or there is distant metastatic spread, the prognosis is poor. Lung, bone, liver, or brain metastases are present in 20% of patients at diagnosis.

Renal medullary carcinoma

Renal medullary carcinoma is a very aggressive, malignant epithelial neoplasm that occurs almost exclusively in children and young adults with sickle cell trait or sickle cell disease.[120–123] In patients <25 years of age, males are affected three times as often as females. Gross hematuria, abdominal pain, and weight loss are common, although the mass itself is not always palpable. Renal medullary carcinoma arises along the urothelial margin of the renal medulla and grows quickly into the renal pelvis with early vascular and lymphatic invasion. Satellite parenchymal nodules are common and most patients have widely disseminated disease at diagnosis with metastases to the contralateral kidney, liver, lungs, and lymph nodes. Response to chemotherapy and radiotherapy is often poor. US shows a heterogeneous, centrally located, extensively infiltrative, solid intrarenal mass that frequently grows into the renal sinus. Smaller peripheral satellite nodules are common. At CT and MRI, the mass enhances heterogeneously.

Leukemia, lymphoma, and lymphoproliferative diseases

Despite the fact that many children who die with leukemia or lymphoma have histologic evidence of renal infiltration at postmortem examination, clinical and radiographic evidence of renal involvement is much less common during life.[11,124–126] Clinical signs of renal involvement, such as a palpable mass, hematuria, or reduced renal function, rarely precede other

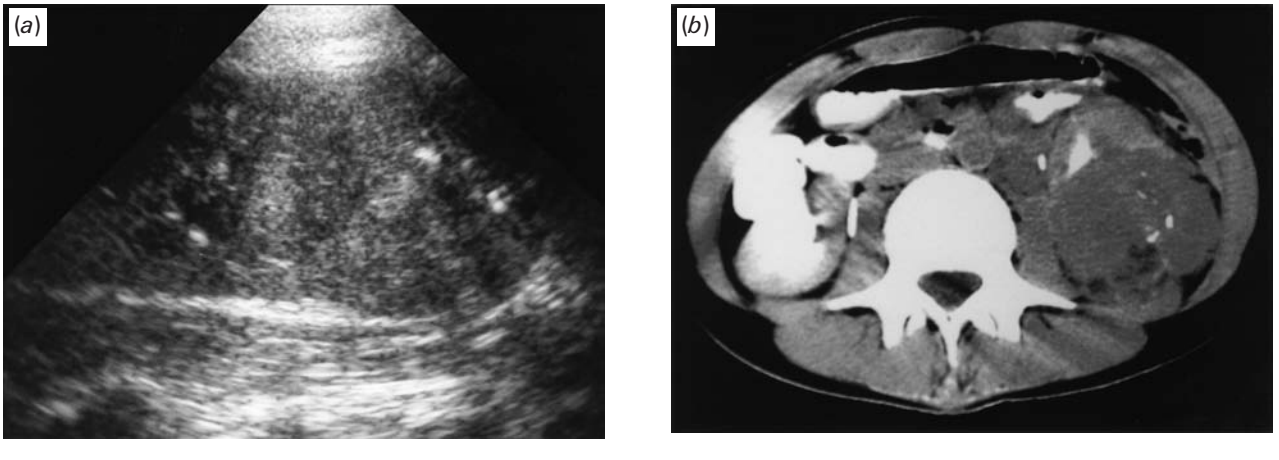

Figure 27.12 A 13-year-old girl with renal cell carcinoma of the lower pole of her left kidney, presenting with abdominal pain and a palpable left abdominal mass. (*a*) Ultrasound: longitudinal view of the left kidney shows a large, solid, slightly heterogeneous lower pole mass. Multiple small calcifications are visible within the mass. (*b*) Contrast-enhanced CT through the kidneys shows a large, solid mass in the lower pole of the left kidney posteriorly. Small calcifications are present within the mass. The residual functioning portion of the left kidney is visible anteriorly.

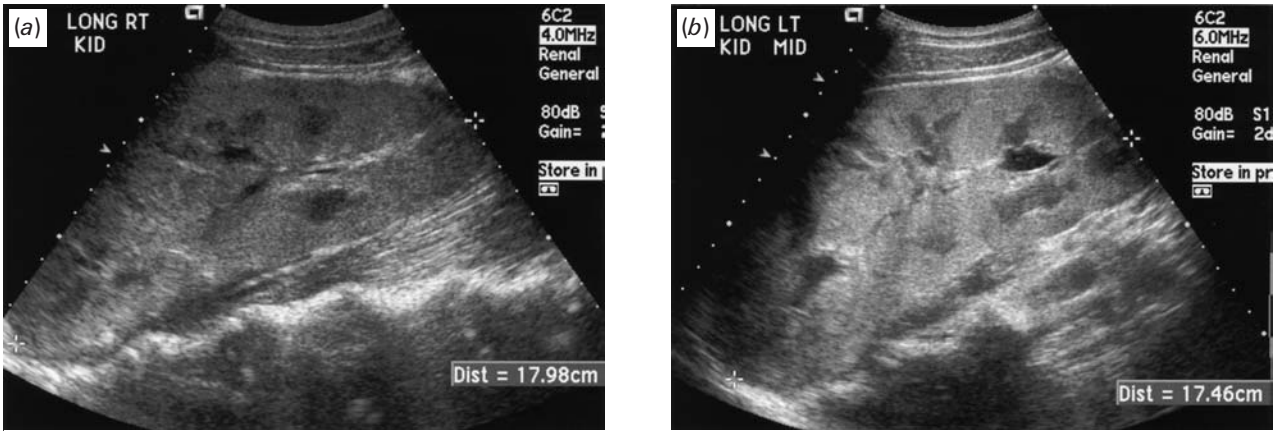

Figure 27.13 An 18-year-old boy with relapsed acute lymphocytic leukemia and diffuse bilateral leukemic renal infiltration. Ultrasound shows markedly enlarged, echogenic kidneys with multiple small, relatively hypoechoic, solid masses scattered throughout the parenchyma bilaterally. (*a*) Ultrasound: longitudinal view of the right kidney (length 18.0 cm). (*b*) Ultrasound: longitudinal view of the left kidney (length 17.5 cm).

manifestations of the disease. As a result, renal involvement is usually detected during staging or follow-up imaging studies in patients who are already known to have disease elsewhere.

Renal involvement is usually bilateral in both leukemia and lymphoma.[11,125,126] Leukemic infiltration of the kidneys causes diffuse renal enlargement, with disruption of the normal corticomedullary architecture (Figure 27.13). Discrete masses are less common in leukemia than in lymphoma. In lymphoma, neoplastic infiltration of the renal interstitium initially also causes non-specific renal enlargement, with diffuse increase in parenchymal echogenicity at US. As the infiltrating neoplastic cells coalesce to form larger, hypoechoic masses, the kidney enlarges and loses its reniform shape. The renal architecture is increasingly disrupted and the parenchyma becomes diffusely more inhomogeneous. At postcontrast CT, multiple coalescing low-attenuation, non-enhancing, solid masses are visible[124,126,127] (Figure 27.14). Perinephric extension and renal hilar and retroperitoneal lymph node involvement is better demonstrated at CT or MRI than at US. Follow-up imaging after successful treatment and regression of the masses often shows extensive cortical defects that can be indistinguishable from other causes of renal atrophy and cortical scarring. Dystrophic parenchymal calcifications are also occasionally seen following treatment for some forms of renal lymphoma (Figure 27.15).

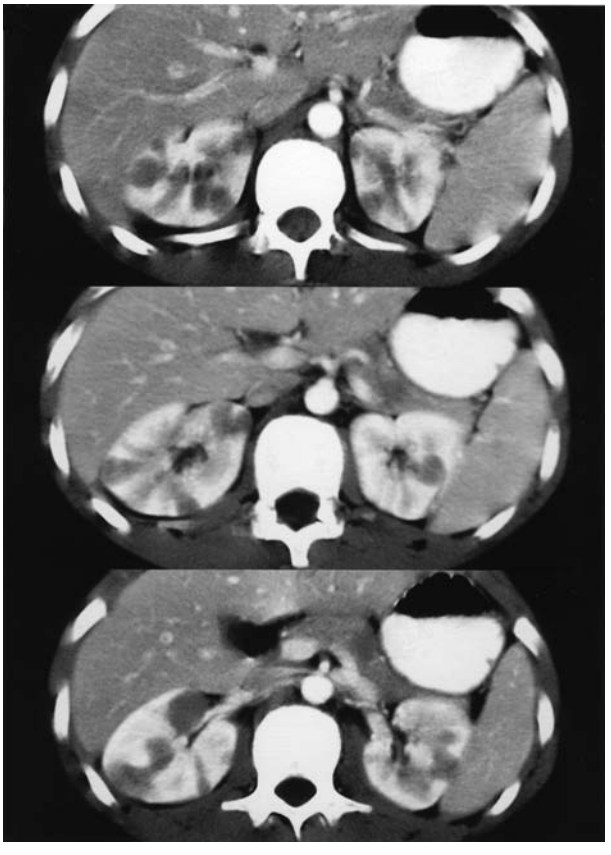

Figure 27.14 A 14-year-old boy with Burkitt's lymphoma of both kidneys. Contrast-enhanced CT shows multiple non-segmental, low-attenuation, non-enhancing solid masses scattered randomly throughout both kidneys.

Lymphoproliferative disorders are an important group of potentially life-threatening conditions that occur in patients who have severely impaired T-lymphocyte-mediated immunity. Lymphoproliferative disorders have been reported as a complication of immunosuppression for organ transplantation[128–130] in primary immunodeficiencies and in acquired immunodeficiency syndrome (AIDS).[50] Regardless of the cause

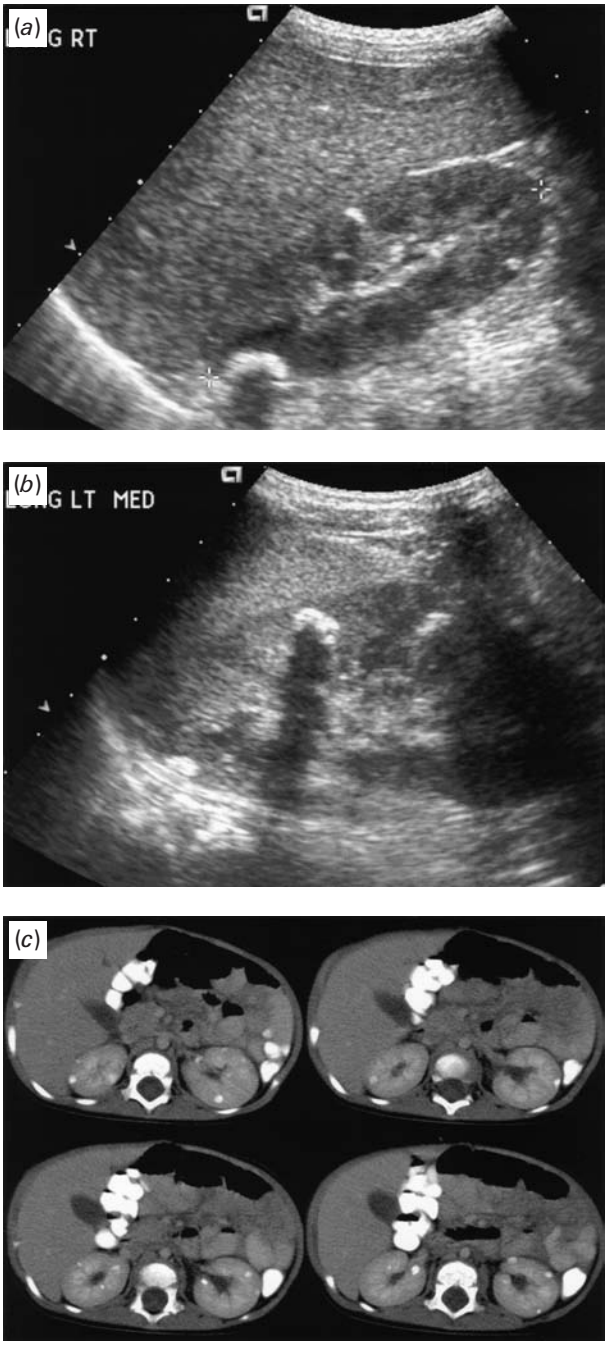

Figure 27.15 A young boy with bilateral dystrophic renal parenchymal calcifications 3 months after treatment for acute myelogenous leukemia. (*a*) Ultrasound: longitudinal view of the right kidney. (*b*) Ultrasound: longitudinal view of the left kidney. (*c*) Contrast-enhanced CT: four axial images through the kidneys.

of the immune defect, Epstein–Barr virus is critical in mediating the induction of polyclonal B-lymphocyte proliferation that leads to the development of lymphadenopathy, focal parenchymal masses, and diffuse infiltration of solid organs.[129,131] Involvement can be focal, multifocal, or widely disseminated, and any organ or body space can be involved. The gastrointestinal tract, solid abdominal organs, and abdominal lymph nodes are most often affected. Renal involvement occurs in 17–20% of cases and has imaging features similar to those of leukemia and lymphoma.

Congenital mesoblastic nephroma (fetal renal hamartoma)

Congenital mesoblastic nephroma (congenital fetal renal hamartoma) is the most common primary, renal tumor in the newborn and occurs almost exclusively in the first year of life.[132–135] Once believed to be a congenital form of Wilms' tumor, mesoblastic nephroma is distinguished by its younger presentation, its characteristically non-aggressive course and limited growth potential, its predominantly mesenchymal derivation, and its lack of a malignant epithelium. Recurrence is unusual as long as the entire mass is removed, although metastatic spread of mesoblastic nephroma to lung and brain has been reported very rarely.[136]

A mass is usually palpable at birth. However, mesoblastic nephroma is increasingly being detected at prenatal US. At US, mesoblastic nephroma appears as a large, solid, renal mass. The mass can be either homogeneous or complex. Cysts are present in 60% of cases and small, scattered calcifications can also occasionally be visible.[137] At CT the tumor presents as a non-enhancing, low-attenuation mass surrounded by enhancing residual normal parenchyma (Figure 27.16). Cystic areas of necrosis

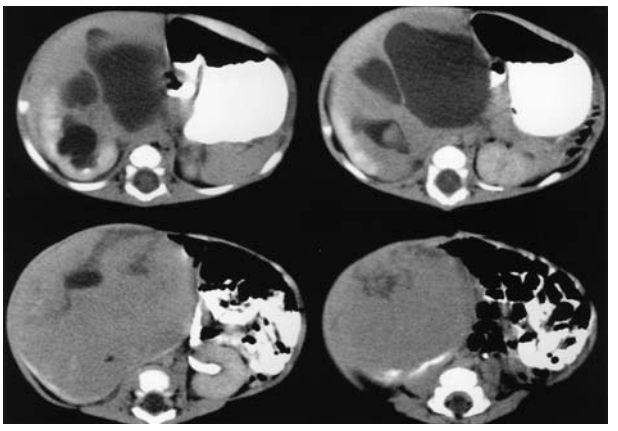

Figure 27.16 An 8-week-old girl with right congenital mesoblastic nephroma, presenting with a palpable right abdominal mass. Contrast-enhanced CT shows a large, solid, non-enhancing right renal mass that compresses the renal pelvis, resulting in obstruction and severe hydronephrosis.

and hemorrhage are readily demonstrated at CT, as are calcifications, when they occur.[133,134]

Multilocular cystic nephroma

Multilocular cystic nephroma is a benign, cystic renal tumor that is made up of non-communicating cysts of differing size separated by thin septa composed of fibrous tissue, tubular elements, and immature blastemal tissue.[138–140] The tumor can involve part or all of the kidney. Rarely, multiple discrete lesions are present. Although the cyst walls occasionally contain cellular elements that are histologically similar to Wilms' tumor, multilocular cystic nephroma has no malignant potential and local recurrence is rare after complete resection.

The imaging features of multilocular cystic nephroma are distinctive.[138,139] The tumor appears as a complex, multicystic mass with uniformly thin septa separating the cysts. The septa are usually more conspicuous at US than CT, although they can enhance somewhat after administration of contrast material. Thicker septa and septa that appear irregular or nodular are unusual in multilocular cystic nephroma and should raise concern that the lesion might instead represent a cystic Wilms' tumor.[140] Septal calcifications are occasionally present in adults, but are rarely seen in children. At MRI, the tumor capsule and septa appear hypointense on both T1- and T2-weighted images, with minimal enhancement after gadolinium.[141] The signal intensity of the fluid within the locules depends on their hemorrhagic and proteinaceous composition.

Angiomyolipoma

Angiomyolipoma is a benign, non-encapsulated, hamartoma of the kidney composed of blood vessels, smooth muscle, and fat.[142–144] In children, angiomyolipoma is very suggestive of tuberous sclerosis and is usually multiple and bilateral (Figure 27.17). Other clinical and imaging features of tuberous sclerosis are usually present. Less often, angiomyolipomas are detected in a child with undiagnosed tuberous sclerosis who presents with a palpable mass or hematuria. Renal cysts also occur in patients with tuberous sclerosis (Figure 27.18) and can coexist with angiomyolipomas.[143–145]

Visualization of fat within a renal mass in a child is highly suggestive of angiomyolipoma.[142–144] Rarely, the tumor has more vascular and muscular elements and contains little or no visible fat. Calcification is usually absent. Angiomyolipomas are usually very echogenic at US and have very low attenuation, similar to perinephric fat on non-enhanced CT scans. At MRI, the tumors are hyperintense on both T1- and T2-weighted images. Because angiomyolipomas are extremely vascular, they enhance very intensely at both CT and MRI. Larger angiomyolipomas tend to bleed, often profusely, resulting in intratumoral, subcapsular, and perinephric hemorrhage.

Renal lymphangioma and lymphangiomatosis

Renal lymphangioma is a rare, benign, cystic renal tumor with imaging features that are similar to multilocular cystic nephroma.[146,147] Renal lymphangioma

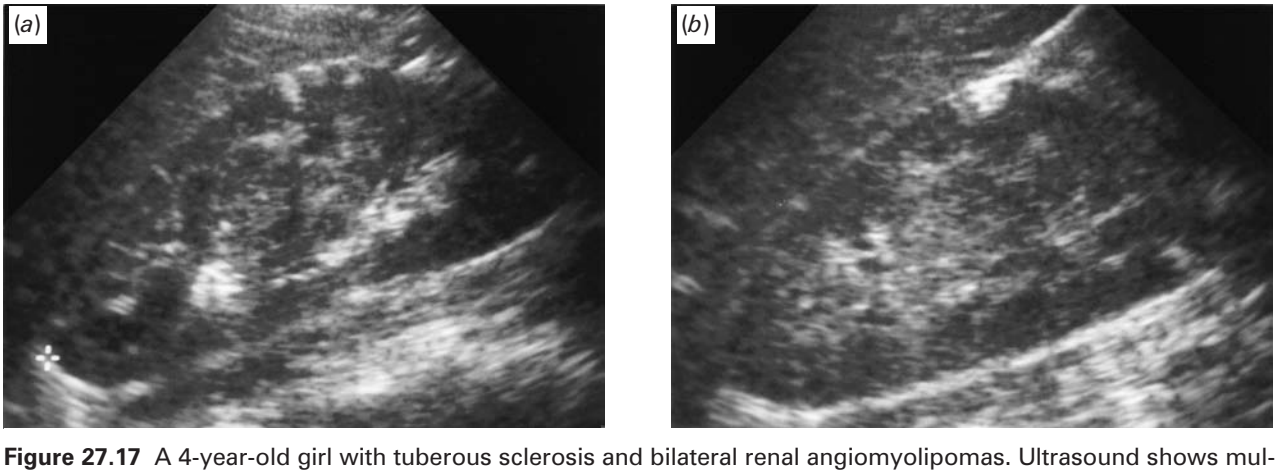

Figure 27.17 A 4-year-old girl with tuberous sclerosis and bilateral renal angiomyolipomas. Ultrasound shows multiple small, solid, non-shadowing echogenic masses scattered throughout both kidneys. (*a*) Ultrasound: longitudinal view of the right kidney (length 7.8 cm). (*b*) Ultrasound: longitudinal view of the left kidney (length 7.9 cm).

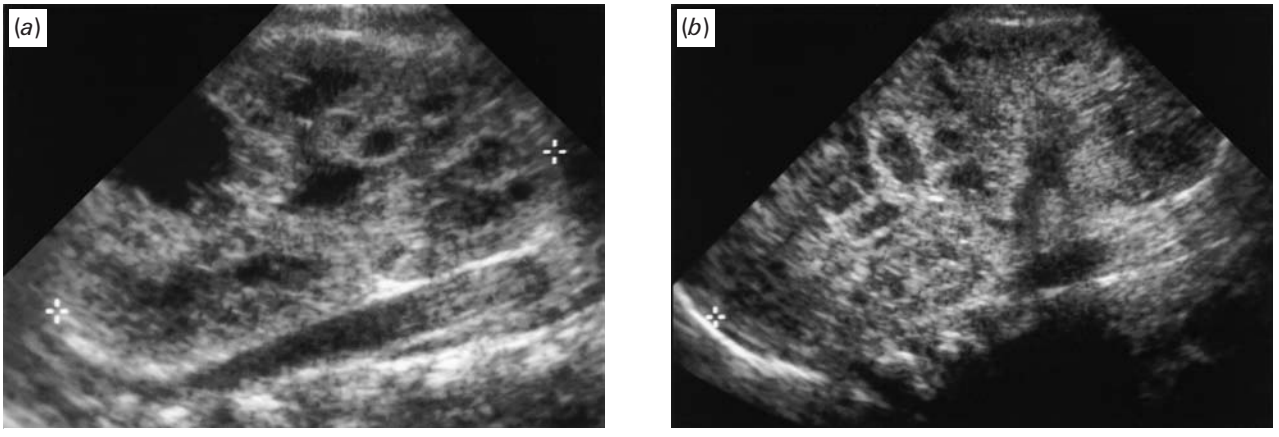

Figure 27.18 A 3-week-old boy with tuberous sclerosis and polycystic kidney disease. The kidneys are both enlarged and heterogeneous with numerous irregular cysts bilaterally. (*a*) Ultrasound: longitudinal view of the right kidney (length 7.0 cm). (*b*) Ultrasound: longitudinal view of the left kidney (length 7.9 cm).

can be either unilocular or multilocular and is usually solitary, although multiple lymphangiomas can occur. Renal lymphangiomatosis is a very rare disorder that is characterized by massive, bilateral nephromegaly with residual functioning islands of renal parenchyma appearing as irregular bands separating the innumerable cysts, simulating the appearance in advanced autosomal dominant polycystic kidney disease or tuberous sclerosis.[148] Lymphangiomatosis can be limited to the kidneys or can occur in association with more extensive retroperitoneal involvement. Cystic pulmonary lesions can also coexist.[149]

Renal cystic diseases

Ultrasound is the primary imaging modality that is used in renal cystic diseases.[5,6,11,150] CT and MRI are generally reserved for those cases in which either the sonographic appearances are uncertain or complications such cyst rupture, hemorrhage, or neoplasm are suspected.

Because isolated, simple renal cysts occur only very rarely in children,[5,6,151,152] the presence of renal cysts in a child should at least lead to consideration that these might be manifestations of an underlying renal disorder such as polycystic kidney disease or renal dysplasia. On the other hand, many cystic renal lesions that are identified at US in children are not cysts in the strict sense. Caliceal diverticula, dilated calices, and even very prominent and hypoechoic medullary pyramids are all very common and should not be mistaken for cysts.

At US, renal cysts appear as round or ovoid, thin-walled, fluid-filled structures.[11,50,150–152] The fluid within uncomplicated cysts is anechoic and the wall is thin and slightly hyperechoic. Cellular, purulent, or proteinaceous debris or blood clot in complicated cysts causes the fluid to appear more echogenic. Particular debris within the cyst fluid is best visualized at US. The fluid in uncomplicated cysts is of homogeneously low attenuation at CT and has low signal intensity on spin-echo and inversion recovery T1-weighted MRI images.[42,153,154] On spin-echo T2-weighted images, the signal intensity of the fluid increases and the wall of the cyst and the fluid may not be distinguishable. Although larger clots within cysts can often be identified at CT, differences in fluid composition and small particulate debris within the cyst fluid are more readily identified at MRI. The signal intensity in hemorrhagic cysts is generally brighter and more inhomogeneous on both T1- and T2-weighted images, but can vary considerably depending upon the age of the hemorrhage and the relative proportions of hemoglobin, deoxyhemoglobin, and hemosiderin. Mural calcification is rare in children in renal cysts, although it is well described in adults. Mural calcifications are best evaluated at CT or US, although larger calcifications are sometimes identifiable at MRI as a signal void within the cyst wall.

Caliceal diverticulum

Caliceal diverticulum is an urothelium-lined, saccular, outpouching of the collecting system that typically arises from one of the caliceal fornices.[42,88,155,156] Caliceal diverticula are believed to be congenital lesions. Rarely, a cyst, hematoma, or abscess that ruptures into a calyx will form a permanent communication

with the collecting system and be can indistinguishable from a congenital diverticulum.

At US, caliceal diverticulum appears as a cystic lesion and is characteristically located centrally in the kidney, adjacent to the pyramids and collecting system.[42,88,155,156] Caliceal diverticula range in size from several millimeters to many centimeters. Individual diverticula can also vary considerably in size, depending upon the degree to which they are distended. Most diverticula communicate freely with the collecting system and will be opacified during either antegrade or retrograde urography as well as during postcontrast CT and MRI. However, when the neck of the diverticulum is stenotic, the fluid within the diverticulum will opacify only faintly or not at all. Comparison of the attenuation within the diverticulum on non-enhanced images with similar measurements on delayed postcontrast images may increase the chance of detecting faint opacification in a stenotic diverticulum. At non-enhanced CT and MRI, caliceal diverticula will similarly be difficult to differentiate from other centrally located cystic lesions.

Autosomal recessive polycystic kidney disease

Autosomal recessive polycystic disease is manifested by severe dilatation and ectasia of the interstitial portions of the collecting tubules.[157] At US, the kidneys are usually dramatically enlarged and inhomogeneously echogenic.[11,50,151,158,159] The echogenic appearance of the parenchyma relates to the abnormally increased reflectivity of the walls of the distended and ectatic tubules. The compressed renal cortex is studded with innumerable tiny cysts and appears as a relatively hypoechoic marginal halo around the kidney and occasionally around the individual renal lobes[158–160] (Figure 27.19). The same architectural changes are visible at CT, although the appearance is typically the video inverse of US, with relatively poorly enhancing ectatic tubules producing a peripherally radiating striated appearance to the enlarged central portions of the individual renal lobes surrounded by brightly enhancing compressed cortex studded with countless tiny cysts.[42]

Autosomal dominant polycystic kidney disease

When autosomal dominant polycystic disease presents in childhood the cysts are usually small and few in number early in life.[5,11,42,151] In neonates, the kidneys appear large and contain multiple small cysts, mimicking the appearance of the recessive form of the disease.[161] As the child becomes older, the cysts increase in size and number. Mural calcification is only rarely seen in children. Complications such as hemorrhage within a cyst can be visualized either at CT or MRI (Figure 27.20). MRI often shows striking differences in the signal intensity of the fluid in the cysts, reflecting differences in protein content of the fluid.[162]

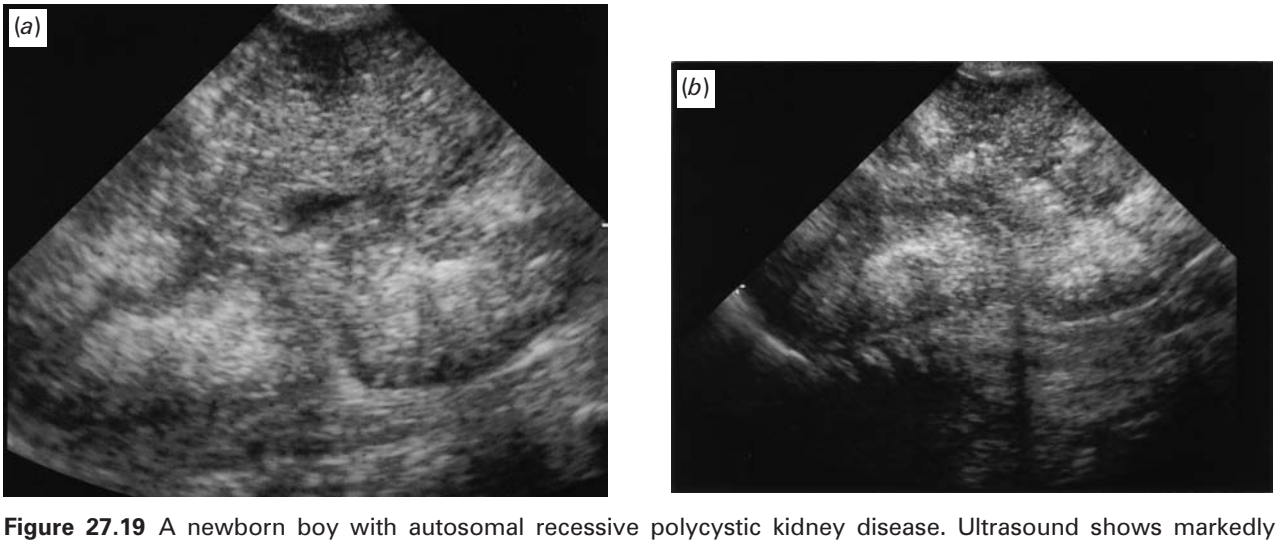

Figure 27.19 A newborn boy with autosomal recessive polycystic kidney disease. Ultrasound shows markedly enlarged kidneys, with accentuation of the renal lobar anatomy. The medullary portions of the renal lobes appear enlarged and very echogenic and are surrounded by a thin peripheral cortical halo. No larger macrocysts are visible. (*a*) Ultrasound: longitudinal view of the right kidney (length 12.7 cm). (*b*) Ultrasound: longitudinal view of the left kidney (length 13.2 cm).

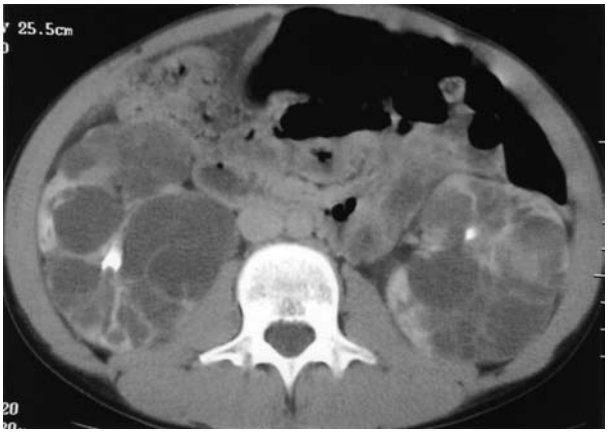

Figure 27.20 A 12-year-old girl with autosomal dominant polycystic kidney disease, presenting with abdominal pain and hematuria after a minor motor vehicle accident. Contrast-enhanced CT shows the kidneys to be almost entirely replaced by numerous large cysts, with strands of residual enhancing parenchyma visible between the cysts.

Glomerulocystic disease of the kidney

The characteristic histologic feature of glomerulocystic kidney disease is cystic dilatation of the space within Bowman's capsule surrounding the glomeruli.[11] Glomerulocystic kidney disease is a rare disorder that is frequently indistinguishable, based on its imaging and clinical features, from classic recessive polycystic disease in the neonate and from some cases of dominant polycystic kidney disease. Autosomal dominant transmission has been suggested in some lineages, with the parents of the affected infants presenting the classic imaging appearances of dominant polycystic disease. Liver disease similar to that in recessive polycystic disease can also occur. Glomerulocystic kidney disease also occurs in trisomy 13, oro–facial–digital syndrome, Zellweger syndrome, tuberous sclerosis, and Meckel–Gruber syndrome, and similar histologic changes are seen in some patients with renal dysplasia. Such widespread clinicopathologic overlap has led some clinicians to suggest that glomerulocystic kidney disease might in reality represent a non-specific histologic appearance rather than a specific disease.[163]

The imaging findings of countless small cysts in a predominantly cortical and subcapsular distribution suggests the diagnosis of glomerulocystic kidney disease.[11,159,164–167] The kidneys are often enlarged in neonates with this disorder, although often not as dramatically as in classic recessive polycystic disease, and the kidneys can decrease in size over time without apparent deterioration in renal function. In other cases, the appearance progresses over time to that typical of dominant polycystic disease. Because of the considerable overlap in the imaging appearances between this disorder and other more common forms of polycystic kidney disease, definitive diagnosis may ultimately require biopsy, where clinically justified.

Medullary cystic diseases

Juvenile nephronophthisis and adult-onset medullary cystic disease of the kidney are both familial forms of chronic tubulointerstitial nephritis that are associated with a urinary concentrating defect and progressive azotemia.[11,167–171] Medullary cysts are present in both diseases. However, the clinical manifestations and patterns of transmission are different. Juvenile nephronophthisis is an autosomal recessive disorder that primarily affects children and is characterized clinically by polyuria, growth failure, and progressive renal insufficiency, usually leading to death in later childhood. Juvenile nephronophthisis is frequently associated with a variety of extrarenal abnormalities, including retinitis pigmentosa, cone-shaped epiphyses, hepatic fibrosis, and cerebellar aplasia. Adult-onset medullary cystic disease is an autosomal dominant disorder with no extrarenal manifestations that typically presents in the third decade or later and is rarely diagnosed in children.

In juvenile nephronophthisis, the kidneys are small or normal in size at US, with diffusely increased parenchymal echogenicity and medullary cysts.[11,169–171] Although medullary cysts are regarded as a characteristic sonographic feature of juvenile nephronophthisis, increased parenchymal echogenicity with loss of corticomedullary differentiation can precede the development of visible macrocysts, resulting in a non-specific appearance in some patients. Very thin-section (1.5 mm) CT or MRI can confirm the presence of medullary cysts in children with atypical sonographic appearances.[167,168,170]

Medullary sponge kidney is a rare, non-hereditary disorder of unknown cause that is characterized by non-progressive medullary ductal ectasia, renal tubular acidosis, hypercalciuria, and nephrocalcinosis.[11] At excretory urography, the appearance reflects the severity of the ductal ectasia.[172] In very mild cases, the medulla has a thinly striated appearance. With more severe involvement, the linear medullary striations first become thicker and then cystic in appearance. Small calculi form within the tubules and the papillae enlarge as the calices become progressively more

distorted. In the most advanced cases, abdominal radiographs reveal nephrocalcinosis, nephrolithiasis, or both. The appearance of multiple clusters of tiny calculi overlying the medullary pyramids is diagnostic of medullary sponge kidney. Calculi that have eroded into the collecting system are visible in the renal pelves, ureters, or bladder. At US, renal size is normal and the medullary pyramids appear hyperechoic as a result of intraluminal calcium deposition.[11,172,173] Shadowing intratubular calculi appear later in the disease. CT is generally inferior to excretory urography in detecting tubular ectasia in medullary sponge kidney and is invariably normal early in the disease. However, subsequently, non-enhanced CT may be better for identifying small intratubular calculi that would be obscured by contrast material at excretory urography.

Renal dysplasia and multicystic dysplastic kidney

Normal nephroureteral development entails a series of complex interactions between the ureteric bud and the developing metanephros, beginning in the 7th gestational week. Failure of these interactions to proceed normally can result in renal dysplasia. Although renal dysplasia is frequently associated with congenital obstructive uropathy,[174–176] it can also occur in the absence of detectable obstruction in patients with severe VUR and as an isolated anomaly.[7,177] Sonographically, dysplastic kidneys are usually small for age or body size and grow slowly. The renal parenchyma appears abnormally echogenic, with reduced or absent corticomedullary differentiation.[5,6,11,178,179] Cysts are present in 40–50% of cases. In cases of severe dysplasia associated with obstruction, the collecting system can be dysmorphic, with poor differentiation of the calices, infundibula, and renal pelvis.[6] When cysts or hydronephrosis are present, the renal measurements may underestimate the reduction in total renal parenchymal volume. At scintigraphy, dysplastic kidneys typically have reduced function, although complete absence of function is uncommon, a feature that is important in distinguishing typical renal dysplasia from multicystic dysplastic kidney (MCDK). Although the appearance at US of a small, echogenic kidney that functions poorly at scintigraphy is usually diagnostic of dysplasia in a neonate, this sonographic appearance is not specific. In an infant or child, a variety of chronic and atrophic renal parenchymal disorders, including interstitial nephritis, chronic glomerulonephritis, and severe reflux nephropathy, as well as renal infarction secondary to acute tubular or cortical necrosis, renal vein thrombosis, or renal arterial obstruction, can be sono-

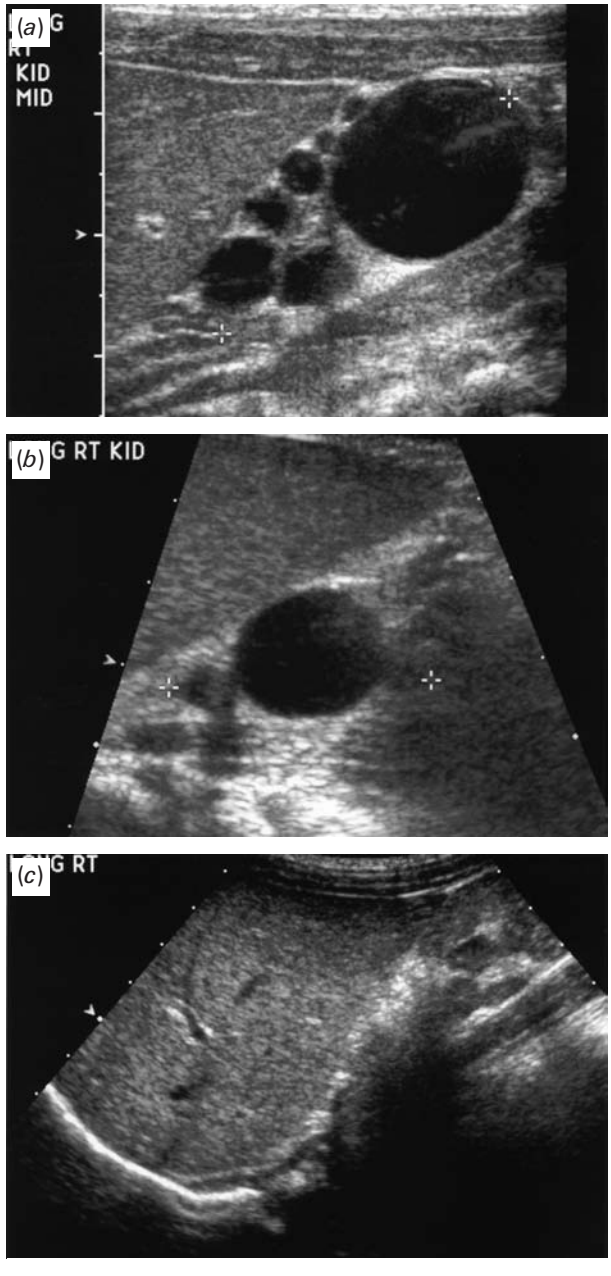

Figure 27.21 A newborn boy with right multicystic dysplastic kidney and subsequent involution. (*a*) Ultrasound: longitudinal view of the right kidney at 2 days old shows the right kidney (length 4.2 cm) is entirely replaced by multiple non-communicating cysts of different sizes separated by thin bands of echogenic, dysplastic parenchyma. (*b*) Ultrasound: longitudinal view of the right kidney at 8 months old shows all of the cysts have decreased in size and the kidney now measures 3.1 cm in length. (*c*) Ultrasound: longitudinal view of the right renal fossa at 18 months old shows no residual visible cysts or right kidney.

graphically indistinguishable from renal dysplasia in the absence of suggestive historical or biochemical information or previous imaging studies.[6,178,179]

In MCDK, atresia of the ureteral bud at or just below the ureteropelvic junction early in nephrogenesis results in a severely dysplastic, non-functioning, cystic kidney.[6,180–182] The diagnosis of MCDK is usually easily established based on characteristic imaging findings at US and renal diuretic or cortical scintigraphy of a non-functioning kidney that is replaced by multiple non-communicating cysts with no residual normal-appearing parenchyma.[6,182] At CT and MRI, the kidney is replaced by multiple cysts of different sizes that are separated by a small amount of non-functioning, dysplastic parenchyma (Figure 27.21). In the hydronephrotic variant of multicystic dysplasia, the kidney is non-functioning and contains one or more smaller peripheral cysts, with a large central cyst representing a rudimentary, dilated collecting system.[181] In segmental MCDK, the anomaly affects only one moiety of a partially or completely duplicated collecting system. When bilateral, MCDK is incompatible with extrauterine life and is usually accompanied by severe oligohydramnios, pulmonary hypoplasia, and other features of Potter's syndrome.

In most patients with MCDK, the fluid within the cysts is gradually absorbed and the kidney progressively decreases in size until it is no longer identifiable at US[183–186] (see Figure 27.21). Because the dysplastic renal remnant has no function, it will not be identifiable at renal scintigraphy. This process of 'involution' ultimately results in an appearance that is indistinguishable from unilateral renal agenesis.[187]

Assessment of renal obstructive disorders: ultrasound, nuclear medicine, and magnetic resonance imaging

28

James Elmore and Andrew J Kirsch

The widespread use of maternal sonography and the routine radiographic evaluation of children with febrile urinary tract infections have resulted in the increased diagnosis of both antenatal and postnatal hydronephrosis. Hydronephrosis is the most common abnormality detected by prenatal ultrasound (US) and is seen in an estimated 1 in 100 to 1 in 500 pregnancies.[1] One of the most important distinctions in the assessment of these children is determining which patients would benefit from surgery and which patients can be safely observed. This distinction is important since unnecessary intervention exposes patients needlessly to the morbidity of surgery, whereas inappropriate observation places patients at risk for infection and renal parenchymal loss.

The common pediatric renal obstructive disorders are listed in Table 28.1. Of these, ureteropelvic junction obstruction (UPJO) is the most common and accounts for nearly half of all prenatally detected uropathies.[1] Ureterovesical junction obstruction (UVJO), ureteroceles, and ectopic ureters are responsible for the majority of the remaining cases. The natural history of renal pelvic dilatation is largely related to the underlying diagnosis. For example, hydronephrosis secondary to an ectopic ureter is unlikely to resolve spontaneously, whereas patients with megaureter can often be followed for years without renal functional loss.[2] The outcome of patients with UPJO is more variable and, as a result, management is more controversial. Some clinicians recommend early surgery, whereas others advocate simple observation.[3–5] Regardless, most urologists will initially follow hydronephrotic kidneys conservatively and use decreasing differential renal function or worsening hydronephrosis as an indicator that surgery may be required.

Table 28.1 Causes of pediatric hydronephrosis

Obstructive causes
Ureteropelvic junction obstruction (UPJO)
Ureterovesical junction obstruction (UVJO)
Ectopic ureters
Ureteroceles
Posterior urethral valves
Urethral atresia
Anterior urethral valves
Congenital urethral stricture
Non-obstructive causes
Vesicoureteral reflux (VUR)
Primary non-obstructive megaureter
Megacalicosis
Fetal folds
Neurogenic bladder
Conditions mimicking hydronephrosis
Extrarenal pelves
Multicystic dysplastic kidney (MCDK)
Peripelvic cysts
Neonatal kidneys (sonolucent renal sinus)

Radiographic approaches to the diagnosis and assessment of renal obstructive disorders have evolved significantly over the past several decades. Intravenous urography (IVU) and the antegrade pressure–flow test, referred to as the Whitaker test, were once mainstays in the evaluation of these patients and are now only rarely used. Technologic advances have given way to US, diuretic renal scintigraphy (DRS), and, more recently, magnetic resonance imaging (MRI) for the evaluation of hydronephrosis. Voiding cystourethrography (VCUG) is frequently performed in conjunction with these studies to rule out

Table 28.2 Advantages and disadvantages of various diagnostic modalities for the assessment of renal obstructive disorders

Imaging study	Advantages	Disadvantages
Intravenous pyelography	Good anatomy if function is good	Inaccurate if poor function; nephrotoxic contrast; radiation exposure
Whitaker test	Only study that measures directly the pressure in the renal pelvis/bladder	Invasive; not reproducible; no functional information; radiation exposure
Ultrasound	Inexpensive, portable, no contrast or radiation exposure	No functional information; limited anatomy
Diuretic renal scintigraphy	Good functional and drainage information	Limited information in bilateral disease; no anatomic information; interpretative error; 15% false negative/positives
Gadolinium-enhanced MR urography	Superior anatomic and functional information even if poor function or bilateral disease; no radiation; contrast non-nephrotoxic	Expensive; not yet widely available; requires sedation and monitoring

vesicoureteral reflux (VUR) as the cause of hydronephrosis. Each of these diagnostic modalities has relative advantages and disadvantages (Table 28.2). In general, these studies provide either good anatomic or good functional information, whereas none of these studies, save MRI, provide both. Some tests are more invasive than others, which also influences test selection. Currently, no study is considered a gold standard for the evaluation of renal obstructive disorders and complete assessment typically involves a series of studies, including US, VCUG, and DRS. Consequently, a thoughtful diagnostic strategy is necessary to proceed with appropriate management at minimal cost and morbidity to the patient.

Ultrasonography

Ultrasonography (or ultrasound) constitutes a cornerstone in the radiologic evaluation of renal obstructive disorders. It is non-invasive, inexpensive, portable, does not require ionizing radiation or contrast media, and is not limited by renal failure. As a result, US is ideally suited as a screening study and for following patients with known abnormalities. A properly performed study provides information regarding renal size, cortical thickness and architecture, and the degree of dilatation of the collecting system. Nomographic charts are available that give 'normal' renal lengths for children of varying ages and body weights (Figure 28.1). The sonographic examination, however, is operator dependent and a skilled sonographer is essential for informative and reproducible studies. The US examination may be limited by body habitus, overlying bowel gas, and poor patient cooperation.

The hallmark finding of hydronephrosis on US is separation of the hyperechoic central renal sinus by anechoic branching structures that represent the dilated calices. With more chronic and severe forms of hydronephrosis, cortical thinning may be seen. Often, if the process is unilateral and leads to renal parenchymal loss, the contralateral kidney may undergo compensatory hypertrophy in young children. In moderate and severe UPJO, pronounced caliceal and renal pelvic dilatation may occur, giving the kidney a classic 'bear paw' appearance on US (Figure 28.2). The ureters can usually only be seen on US if they are dilated, and the presence of a dilated ureter lying posterior to the bladder helps distinguish megaureter from UPJO. When either diagnosis is a consideration, a VCUG to rule out VUR as the cause of dilatation should be performed. It should be kept in mind that VUR may coexist with UPJO in as many as 10% of children.[7]

The Society for Fetal Urology (SFU) has proposed a grading system for reporting hydronephrosis detected by US.[8] This system takes into consideration the appearance of the calices, renal pelvis, and parenchyma to grade the degree of hydronephrosis from I to IV (minimal to severe). SFU grades I and II represent mild to moderate degrees of pelviectasis and should not be considered hydronephrosis. Grades III and IV represent true hydronephrosis, grade IV being the most severe with cortical atrophy (Table

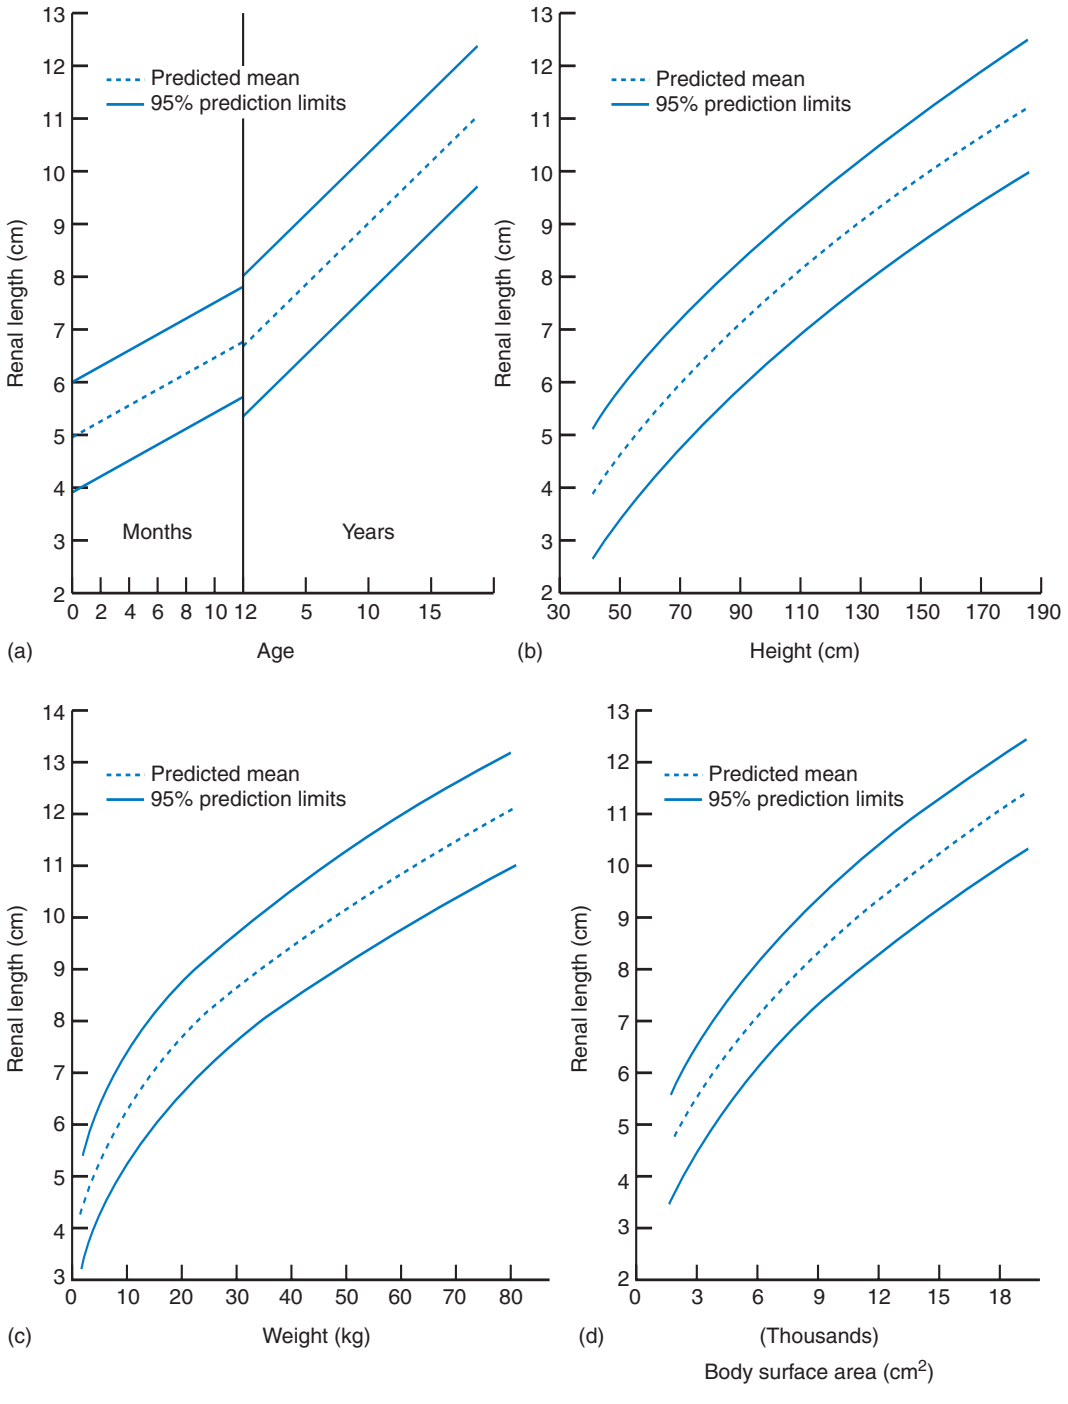

Figure 28.1 Renal nomographic chart. (Adapted from Han and Babcock.[6])

28.3). The degree of hydronephrosis is used to assist in decision making with regard to treatment and, additionally, provides some prognostic information. For example, SFU grades I and II hydronephrosis secondary to UPJO have a tendency to resolve with time and usually only require a VCUG to rule out VUR and sonographic re-evaluation. For SFU grades III and IV, some type of functional evaluation, in addition to a VCUG, is usually recommended since these patients are more likely to have significant urologic pathology and to require surgical intervention.

Although controversy exists over size cut-offs, there is a well-documented correlation between the anteroposterior diameter (APD) of the renal pelvis on prenatal ultrasound and the probability that a significant postnatal pathology will be present. Most authors use an upper limit of normal of 5 mm APD before 30 weeks of gestation, and up to 10 mm later in

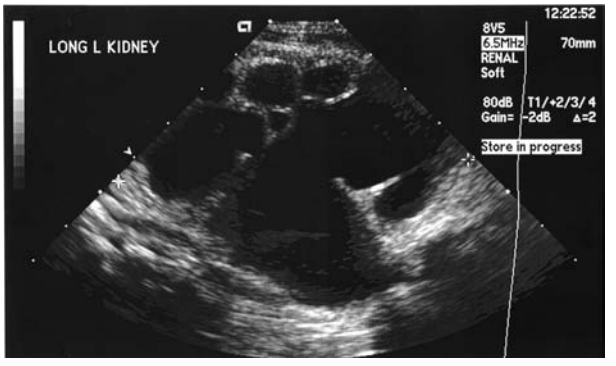

Figure 28.2 A 6-year-old boy with left ureteropelvic junction obstruction. Note the massive renal pelvic and caliceal hydronephrosis, giving the kidney the appearance of a 'bear paw' on ultrasound.

Table 28.3 SFU grading scale for hydronephrosis detected by US

Grade	Central renal complex (pelvis and calices)	Renal parenchyma
I	Slight splitting	Normal
II	Evident splitting; confined within renal border	Normal
III	Wide splitting; pelvis dilated outside renal border; calices dilated	Normal
IV	Wide splitting with pelvis dilated outside renal border; calices dilated and may appear convex	Atrophy

From Fernbach.[9]

pregnancy.[10] Bouzada et al found that an APD of >15 mm on postnatal US had a sensitivity of 100% and a specificity of 92.5% for identifying renal units that ultimately required pyeloplasty.[11] Similarly, Johnson et al found that 11 (79%) of 14 kidneys with an antenatal APD of >15 mm were obstructed or demonstrated VUR on postnatal evaluation.[12] Finally, a prospective trial undertaken at the Great Ormond Street Hospital demonstrated that the severity of renal pelvic dilatation is useful for predicting renal functional deterioration and the eventual need for surgery in the management of UPJO (Table 28.4).[13]

The term hydronephrosis implies obstruction, and exposes an important limitation of US. No functional information is obtained from conventional US, and obstruction cannot be diagnosed based solely on anatomic information. Therefore, although US is

Table 28.4 Correlation between anteroposterior diameter (APD) of the renal pelvis and requirement for surgical intervention

Maximal APD[a] of renal pelvis (mm)	Risk of requirement for surgical intervention (based on functional criteria) (%)
<15	2
15–20	7
20–30	29
30–40	61
40–50	67
>50	100

[a] The APD refers to the maximum size encountered at any stage on pre- or postnatal US. Findings derived from prospective studies undertaken at the Hospital for Sick Children, Great Ormond Street, London.[4]

highly accurate in the diagnosis of renal dilatation, it is not reliable in predicting obstruction or providing information regarding renal function. Even in the presence of renal pelvic dilatation secondary to an obstructive process, the degree of dilatation does not necessarily reflect the degree of, or functional significance of, the obstruction. Indeed, numerous cases have been reported of mild dilatation with complete obstruction and marked dilatation when no obstruction is present. False-positive studies may result from an extrarenal pelvis, a peripelvic cyst, residual dilatation from previous obstruction, dilatation resulting from VUR, and pyelonephritis. The fetal and neonatal kidney may also appear hydronephrotic on US secondary to the sonolucent appearance of the medulla and pyramids (Figure 28.3). False-negative studies

Figure 28.3 Left kidney of healthy neonate by ultrasonography. Note the relatively sonolucent renal sinus, which may be mistaken for hydronephrosis.

are less frequent, but obstruction may be present in the absence of dilatation in acute obstruction and in certain extrinsic processes such as metastases and retroperitoneal fibrosis. Oliguric states may also lead to false-negative studies. This is particularly true in the newborn, in whom renal sonography may underestimate or completely overlook renal dilatation because of the oliguric state of the healthy newborn. It is rare that this results in missing significant renal obstruction, however.

Duplex Doppler ultrasonography

Given the limitations of conventional US in distinguishing obstructive from non-obstructive causes of hydronephrosis, duplex Doppler US has recently been shown to have some value in the diagnosis of renal obstructive disorders. This adjunct to US is based on the fact that obstruction causes an increase in intrarenal arterial resistance, resulting in a relative reduction in diastolic flow compared with systolic flow. Renal arterial resistance is quantified using the formula:

$$\frac{\text{peak systolic velocity} - \text{minimum diastolic velocity}}{\text{peak systolic velocity}}$$

The result of this formula is referred to as the resistive index (RI) (Figure 28.4). Different criteria have been proposed to suggest obstruction, including an RI of >0.70, an inter-renal RI difference of >0.06–0.10 with unilateral dilatation, and an abnormal RI response to a diuretic challenge.[15] For children, and especially the neonate and infant, the RI tends to be elevated compared with adult standards. RIs of 0.7–1.0 can be normal in these populations and usually decrease to adult ranges by about 2–4 years of age.[16] Therefore, the latter two criteria appear most helpful in the pediatric age group.

Numerous studies have been performed evaluating the role of duplex Doppler US for the diagnosis of renal obstruction and with mixed results. Kessler et al evaluated the role of RI in distinguishing obstructive uropathy from non-obstructed dilatation in a group of children with unilateral hydronephrosis.[17] The kidneys were prospectively evaluated by using duplex Doppler US and obstruction was confirmed by either renography or at the time of surgery. Using an RI of ≥0.70 plus a difference in the RI between kidneys of ≥0.08 as the criteria for obstruction, they found duplex Doppler US had positive and negative predictive values of 95% and 100%, respectively. They concluded that the RI appears to be an effective parameter for both the evaluation and follow-up of obstructive or non-obstructive dilatation in children. Other clinicians have published less encouraging results. Gill et al studied the undilated urinary tracts of 47 children for the purpose of establishing a nomogram for RI values and to determine if an RI value of <0.7 reliably predicts an unobstructed collecting system.[18] They found that 37% of the normal renal units had an RI >0.70 and concluded that RI values in undilated (i.e. normal) kidneys vary significantly, and the routine use of this technique needs further evaluation. As indicated by these studies, the use of duplex Doppler US for the evaluation of renal obstructive disorders is currently controversial and, as a result, the modality is not widely utilized.

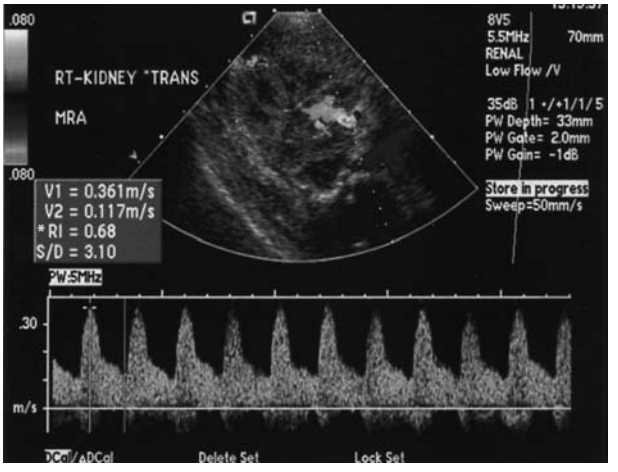

Figure 28.4 Duplex Doppler image taken from a 4-year-old boy. Note the arterial waveform and the normal resistive index (RI) of 0.68 (asterisk).

In summary, US is most commonly utilized as a screening method for the diagnosis of renal obstructive disorders. Although in theory duplex Doppler US can provide useful functional information, in practice other studies are used to better delineate the cause and functional significance of hydronephrosis once it is detected. Most commonly, after VUR has been ruled out by VCUG, the next study of choice is DRS.

Diuretic renal scintigraphy

DRS was developed in the late 1970s as a non-invasive method for evaluating patients with renal obstructive disorders. The introduction of better radiopharmaceuticals and gamma cameras has led to an increased use

of nuclear imaging in pediatric urology. Once hydronephrosis is detected by other imaging methods, usually US, DRS is considered by many to be the preeminent method for estimating differential renal function and characterizing the severity of obstruction. Worsening renal function by DRS is often the impetus for pyeloplasty in patients being observed with UPJO. DRS also remains the most commonly used method for serial follow-up and postoperative assessment of patients with UPJO and megaureter.

The radiopharmaceuticals used for DRS comprise a radionuclide, most commonly technetium 99m (^{99m}Tc), bound to a carrier macromolecule. Renal handling of the various radiopharmaceuticals and, therefore, the information gained from DRS, is dictated solely by the biochemical properties of the carrier macromolecule. The ability to label these macromolecules, which have known physiologic destinations within the body, forms the basis of renal scintigraphy. The principal radiopharmaceuticals used for DRS are ^{99m}Tc mercaptoacetyltriglycine (Tc MAG3), ^{99m}Tc diethylenetriamine pentaacetic acid (Tc DTPA), and ^{99m}Tc dimercaptosuccinic acid (^{99m}Tc DMSA) (Table 28.5). ^{99m}Tc MAG3, one of the newest radiopharmaceuticals, is 90% bound to plasma proteins and is principally cleared by tubular secretion. It shows both the parenchyma and collecting system well and provides excellent functional quantification. These qualities and the fact that it requires lower radiation doses than other radiopharmaceuticals make it the current agent of choice for evaluating renal function and drainage. In contrast, ^{99m}Tc DTPA has little plasma protein binding and is cleared almost exclusively by glomerular filtration. It is rapidly filtered into the urine and therefore provides excellent visualization of the pelvicaliceal system, ureter, and bladder, but may not be retained in the renal parenchyma long enough for good visualization of parenchymal abnormalities. Also, since ^{99m}Tc DTPA relies principally on glomerular filtration, results are often suboptimal in infants with immature kidneys and a low glomerular filtration rate (GFR) or in patients with compromised renal function. In these scenarios ^{99m}Tc MAG3 is the preferred agent. ^{99m}Tc DMSA is unique among the other commonly used radiopharmaceuticals in that it tightly binds to the renal tubular cells and only a small amount is excreted into the urine. Therefore, it allows excellent visualization of the renal parenchyma and is primarily used for evaluating cortical lesions such as scars that occur as a result of pyelonephritis.

The basic principles of DRS are as follows. The radiopharmaceutical of choice is injected intravenously. Normally, during the first 2–3 minutes, renal parenchymal uptake occurs. The radionuclide emits gamma radiation that is detected by a gamma counter. This emitted radiation is temporally and spatially quantified with computer-assisted digital processing and represented morphologically and graphically as a scan (Figure 28.5). This information is analyzed and compared, allowing for the computation of differential renal function (DRF). It is generally accepted that the error in determining the DFR is ±5%. After about 20 minutes, furosemide is injected intravenously to promote diuresis and the velocity and pattern of drainage from the kidneys to the bladder are analyzed. In the absence of obstruction, half of the radionuclide is cleared from the renal pelvis within 10–15 minutes, termed the $T_{1/2}$. A $T_{1/2}$ of >20 minutes indicates obstruction, whereas a $T_{1/2}$ of <15 minutes is generally considered normal. Times between 15 and 20 minutes are indeterminate. Indications for surgical intervention based on DRS generally include DRF of <35–40% and a $T_{1/2}$ of >20 minutes, and US findings consistent with anatomic obstruction. Despite these parameters, neither should be used as an independent variable to determine if obstruction is present or absent.

Table 28.5 Common radiopharmaceuticals used in diuretic renal scintigraphy

Radiopharmaceutical	Renal handling	Application
^{99m}Tc Mercaptoacetyltriglycine (^{99m}Tc MAG3)	Principally cleared by tubular secretion	Renography
^{99m}Tc Dimercaptosuccinic acid (^{99m}Tc DMSA)	Localizes and binds to the proximal convoluted tubules	Renal parenchymal imaging
^{99m}Tc Diethylenetriamine pentaacetic acid (^{99m}Tc DTPA)	GFR dependent for clearance	Renography

GFR, glomerular filtration rate.

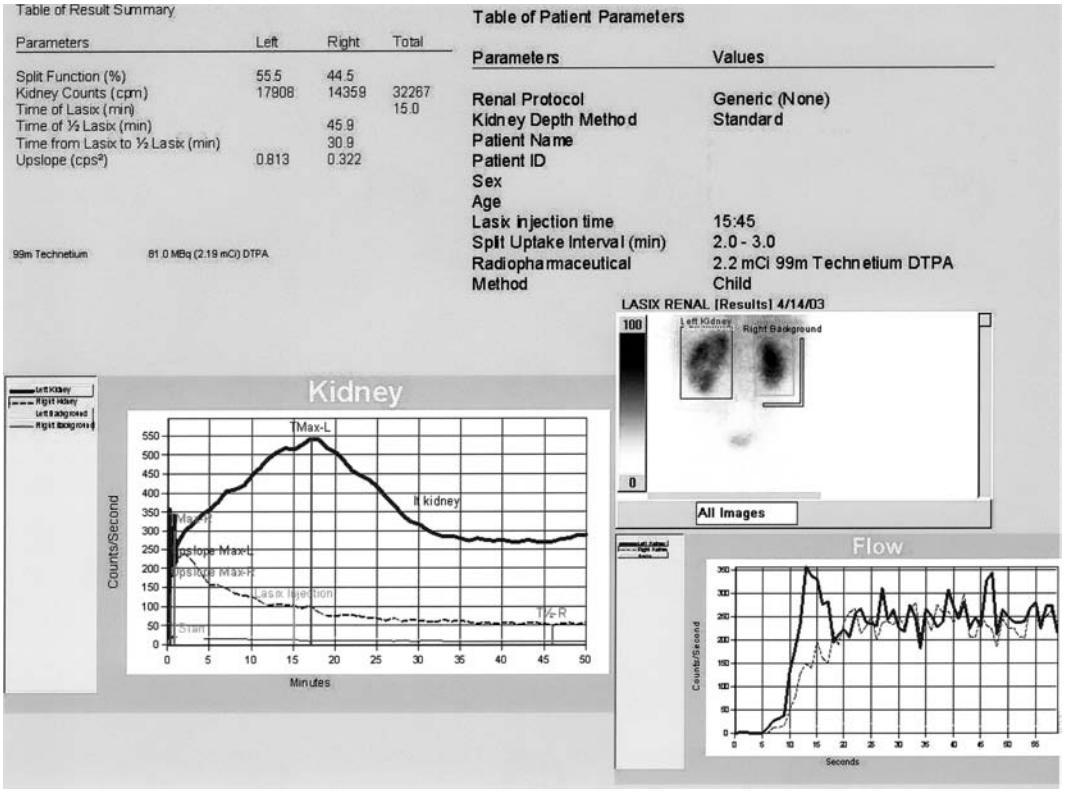

Figure 28.5 Diuretic renal scan (^{99m}Tc MAG3) taken from a 3-year-old boy with severe left ureteropelvic junction obstruction. Note that the $T_{1/2}$ of the left kidney is never reached.

Over the years a wide variety of protocols and techniques for diuretic renography have been used. Unfortunately, this has produced variability in interpretation among different institutions. In an attempt to promote standardization of the technique, the SFU and the Pediatric Nuclear Medicine Council (PNMC) of the Society for Nuclear Medicine published guidelines for the 'well-tempered' diuresis renogram in 1992.[19] Its purpose was to allow easy comparison between studies and institutions. The guidelines standardize many of the facets of the study, including intravenous hydration, bladder catheter placement, patient position, data acquisition and analysis, timing of diuretic administration, and regions of interest for which to monitor the diuretic effect. However, in practice, local protocols are still frequently used, which makes comparing results from different centers problematic.

Despite the widespread use of DRS, there are significant limitations with the technique. For example, DRS only provides differential renal function and, as a result, is less informative in patients with overall poor renal function or solitary kidneys. Caution must be taken when interpreting results in these scenarios. Very capacious collecting systems can also prove problematic, since radionuclide retained in the renal pelvis may be included in the region of interest (ROI) and falsely elevate differential function. Although debatable, this artifact may be responsible for the supranormal function (>55%) reported for some hydronephrotic kidneys.[20] Interpretation is also somewhat subjective and may lead to reporting error (Figure 28.6). Other disadvantages of DRS are its poor anatomic resolution and long examination times. Not infrequently, patients will fall into the equivocal category. These patients may require a repeat DRS, or less commonly, a Whitaker test, to further assess renal obstruction. Overall, DRS may fail to determine the presence or absence of obstruction in at least 15% of cases.[21]

Clearly, there are strengths and weaknesses associated with US and renal scintigraphy. Specifically, whereas US provides useful anatomic information, it provides no functional information. Conversely, renal scintigraphy provides functional information, but little anatomic information. Therefore, although these studies are highly informative in tandem, neither study alone is typically sufficient for making clinical

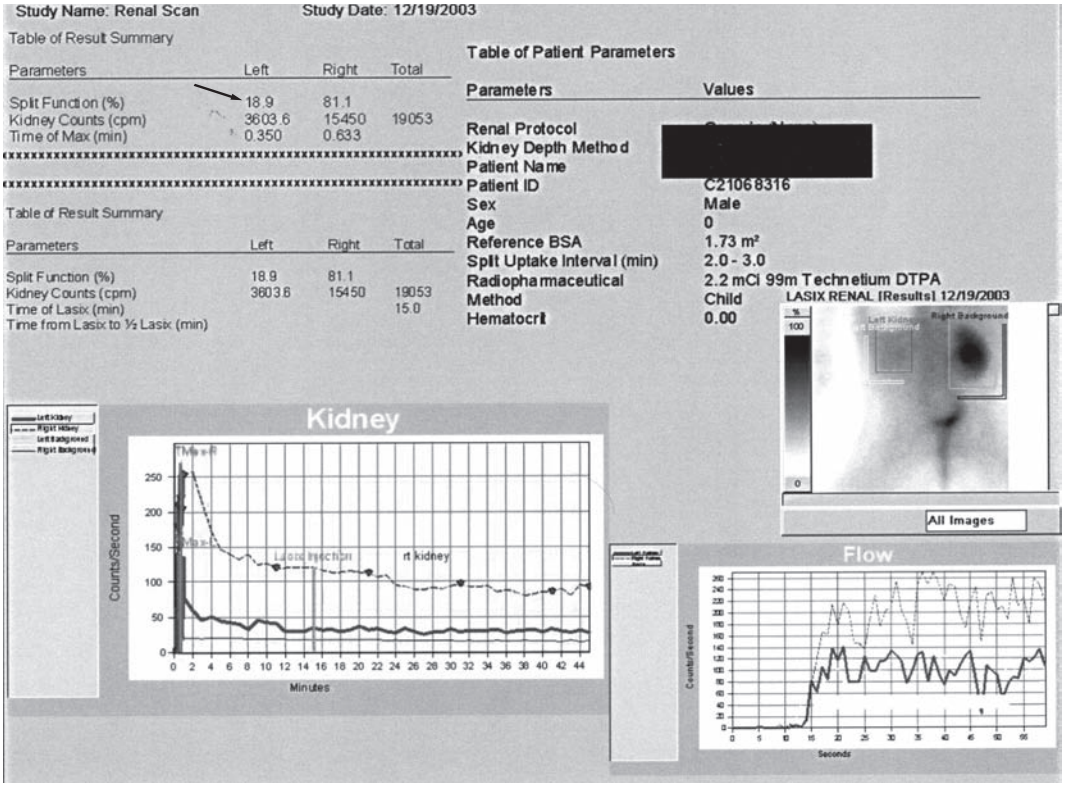

Figure 28.6 Diuretic renal scan from a 3-month-old boy. Note that the scan shows 18% differential left renal function. Further evaluation showed that the patient had a solitary right kidney, which highlights the interpretative error possible with scintigraphy.

decisions. Recently, contrast-enhanced MRI of the urinary tract, as a single study, has been shown to have promise in the investigation of renal obstructive disorders.

Magnetic resonance imaging

The use of magnetic resonance urography (MRU) in the diagnosis of pediatric renal obstructive disorders has increased dramatically since it was introduced in the late 1980s. This has been the result of a series of recent technologic advances that have enabled faster image acquisition, improved resolution, reduced motion artifact, and three-dimensional (3D) reconstruction. Even today, newer imaging sequences and shorter acquisition times are improving image quality and expanding the diagnostic capabilities of MRU. The advantages of MRU for evaluating renal tract anomalies in children are that it has multiplanar capabilities, offers excellent anatomic resolution and soft tissue contrast, and does not use ionizing radiation. Possibly, one of the most important developments occurred in the late 1990s when gadolinium-DTPA (Gd-DTPA) was first used in conjunction with MRU. Gd-DTPA and ^{99m}Tc DTPA share the same carrier macromolecule and are handled by the kidneys in an identical fashion. As a result, Gd-DTPA-enhanced MRU (Gd-MRU) measurements of renal perfusion, uptake, and excretion correlate with those obtained by ^{99m}Tc DTPA renal scintigraphy. Gd-MRU is the only study to date that has the capability of providing excellent morphologic detail typical of MRI as well as functional information that is equivalent or superior to DRS. Even at very low concentrations, Gd-DTPA has high signal intensity on MRI, giving Gd-MRU the ability to reliably detect hydronephrosis and transition in ureteral caliber even in non-functioning systems (Figure 28.7). The results of one study showed that Gd-MRU may be a useful tool for distinguishing an obstructed from a non-obstructed dilated system, even when ^{99m}Tc MAG3 renography results were compromised by reduced renal uptake in the affected kidney.[22] An added advantage is that gadolinium, unlike iodinated contrast agents, is not nephrotoxic and can be used safely in patients with impaired renal function.

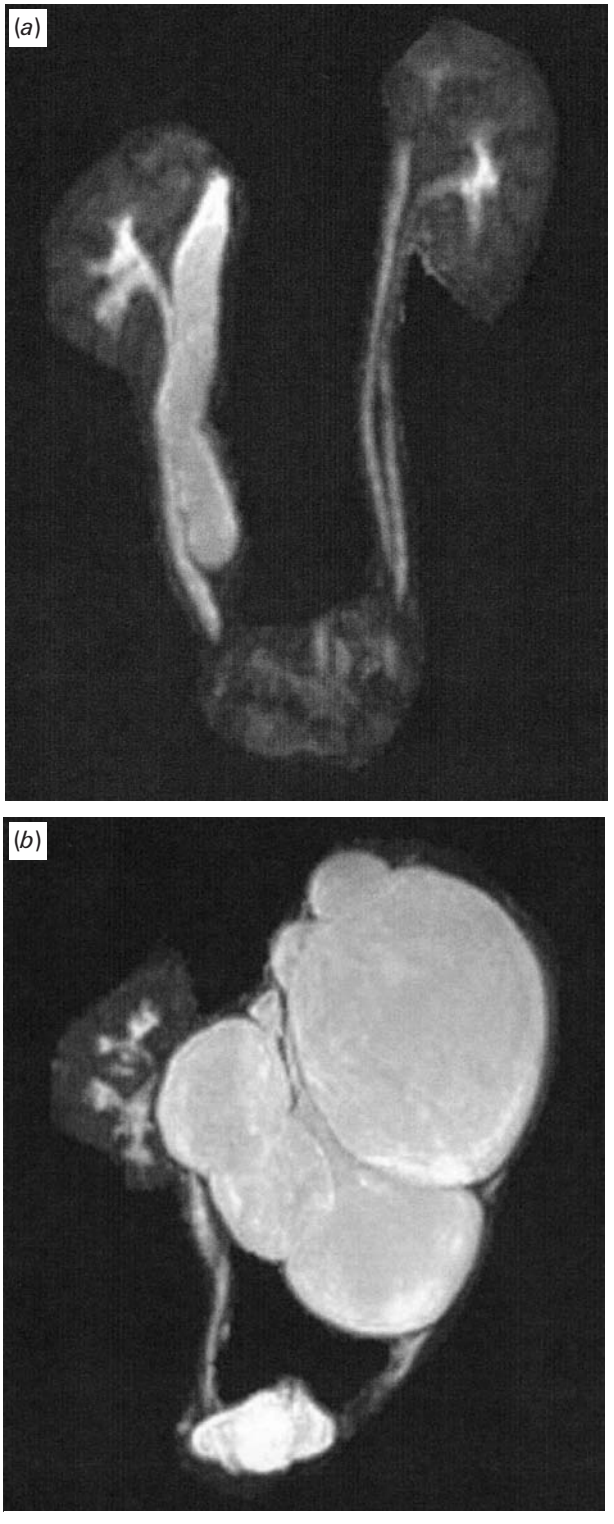

Figure 28.7 Gadolinium-enhanced MRU permits hydronephrosis and transition in ureteral caliber to be reliably detected even in non-functioning systems. (*a*) An 8-year-old patient with a dysmorphic right upper pole, with a dilated ureter down to the pelvis consistent with ureteral atresia. These findings could not be appreciated on either ultrasound or diuretic renal scintigraphy. (*b*) Left multicystic dysplastic kidney that had no function on diuretic renal scintigraphy.

Although protocols for Gd-MRU differ slightly among institutions, the basic principles are preserved. The study involves initial T1- and T2-weighted images through the kidneys, ureters, and bladder. Gd-DTPA is then administered intravenously and dynamic contrast-enhanced T1-weighted imaging using a volumetric gradient echo technique is performed over the entire urinary tract. In a fashion similar to IVU, the uptake, excretion, and drainage of Gd-DTPA can be visualized sequentially. The advantage of Gd-MRU is that, in addition to providing anatomic information which exceeds that of US, computer-assisted postprocessing techniques can be employed to objectively quantify function and the degree of obstruction, similar to DRS.

During postprocessing, image sequences are viewed as cinematic loops. This permits the assessment of renal perfusion and excretion and the generation of signal intensity vs. time curves. Following contrast administration, three distinct phases of enhancement are recognized (Figure 28.8). In the first phase, the renal cortex enhances vividly, differentiating renal cortex from medulla. This is followed by a medullary phase, where the medulla enhances greater than the cortex. The third phase consists of excretion of contrast medium into the collecting system and ureters. Gadolinium transit through these anatomic areas causes a variation in the MR signal intensity over time, which can be represented graphically by signal intensity vs time curves (Figure 28.9). When function is reduced in one kidney, signal intensity is reduced compared with the normal side. The 3D maximum intensity projection (MIP) images from delayed images of the renal pelvis and ureters that exhibit good contrast enhancement provide excellent anatomic resolution of the collecting system and ureters.

The diagnosis of obstruction on MRU is based morphologically on the findings of renal pelvic dilatation and ureteral narrowing. Functionally, obstruction is suggested by reduced enhancement, delayed excretion of contrast into the collecting system and ureter, swirling contrast, and fluid–fluid levels within the renal pelvis. With Gd-MRU, reduced enhancement and delayed excretion can be objectively quantified through the calculation of DRF and the renal transit time (RTT), which are tantamount to the split renal function and $T_{1/2}$ time obtained by DRS. Using a two-compartment mathematical model, referred to as the Rutland–Patlak plot, single kidney GFR can also be calculated with Gd-MRU. This technique enables MRU-based assessment of function in

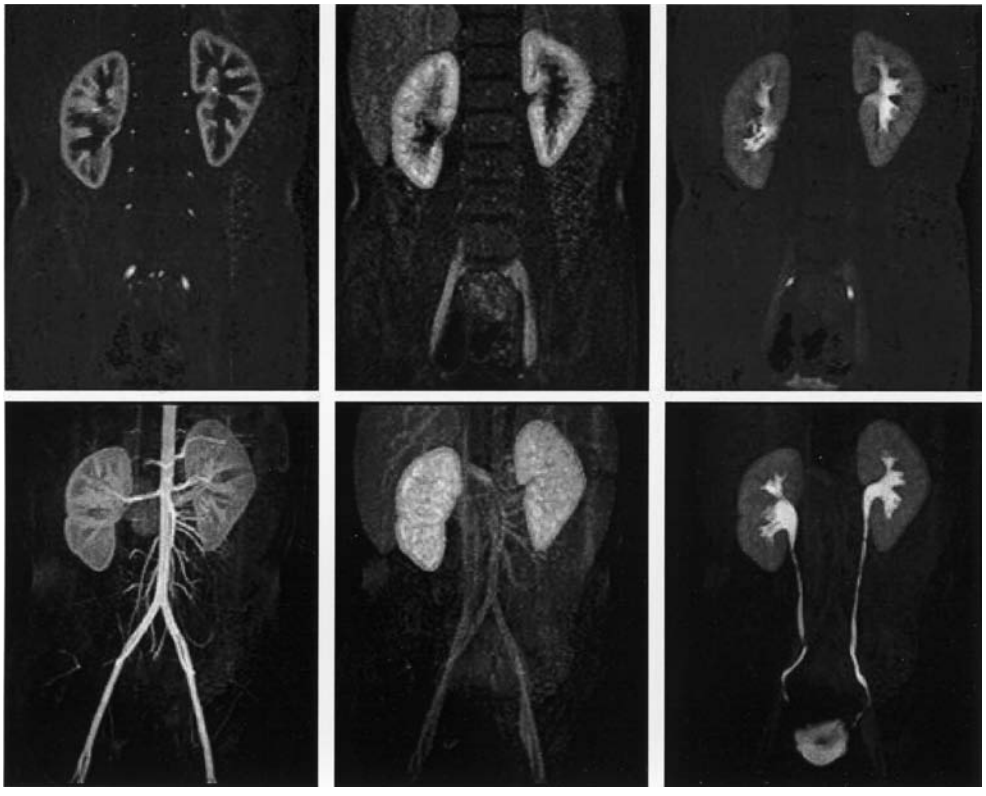

Figure 28.8 Following contrast administration, three distinct phases of renal enhancement can be recognized. Top row: left to right, cortical phase, medullary phase, and excretory phase. Bottom row shows the maximum intensity projections (MIPs) from which images were generated.

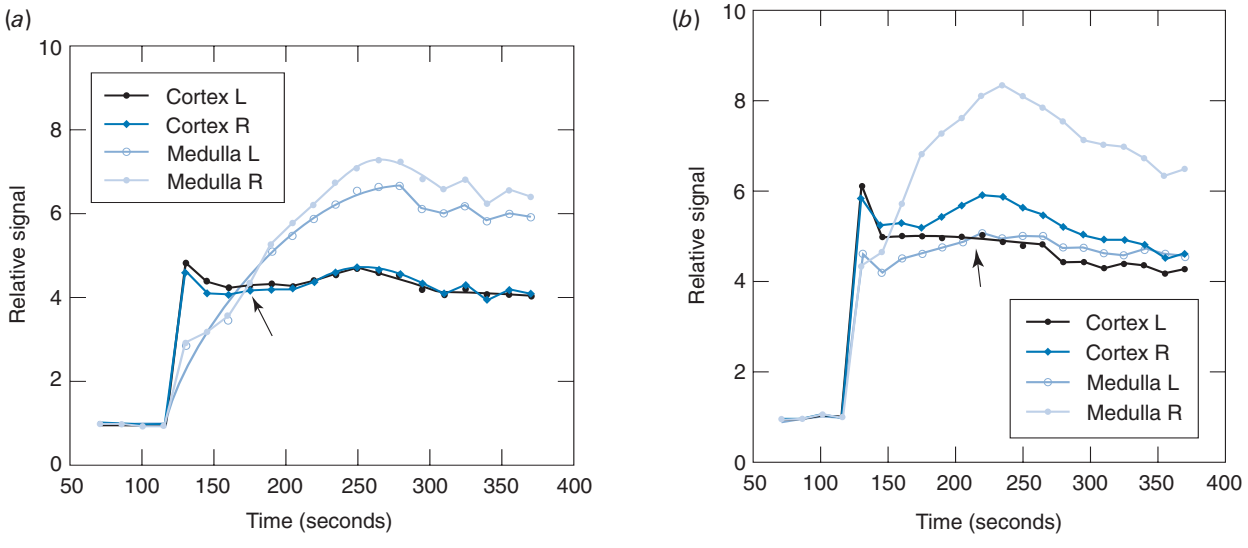

Figure 28.9 (*a*) Normal time–intensity graph. Parenchymal enhancement by MRU occurs in a predictable fashion. The corticomedullary crossover (CMC) point (arrow) is the time at which the medulla has a higher relative signal intensity than the cortex. (*b*) Time–intensity graph taken from a patient with left UPJO. Delayed corticomedullary crossover (arrow) indicates increased intratubular pressure, which is suggestive of obstruction.

patients with bilateral disease or solitary kidneys, a distinct advantage over DRS, which only provides differential information.

DRF is determined using images acquired at the time there is homogeneous enhancement within the kidney but prior to excretion of contrast into the collecting system. With 3D reconstruction, the volume of enhancing renal parenchyma is selected manually as an ROI. Vivid contrast enhancement of the renal parenchyma makes it possible to omit the collecting system and background. DRF is then calculated using the formula:

$$\text{percent renal function} = \frac{\text{individual kidney volume}}{\text{right kidney volume} + \text{left kidney volume}} \times 100.$$

Data published by the authors, as well as that of other clinicians, show a high correlation between DRF as determined by MRU and renal scintigraphy.[23–25] To better determine split renal function, and not volume, we have begun to use Patlak indices of GFR to compare the functional contribution of each kidney to overall renal function (AJ Kirsch and JD Grattan-Smith, unpublished work).

The RTT refers to the time between the appearance of the contrast in the kidney and its appearance in the ureter (below the UPJ) and is based on 3D sequences that allow the passage of contrast to be tracked though the kidneys. Based on the RTT, drainage can be classified as normal (RTT ≤4 minutes), equivocal (4 <RTT ≤8 minutes) or obstructed (RTT >8 minutes).[26] Receiver operating characteristic (ROC) analysis for comparison of results by MRU and DRS shows good agreement between the modalities for the diagnosis of renal obstruction. The unique ability of MRU to provide quantitative functional information such as DRF and RTT, in addition to excellent anatomic characterization of the parenchyma and collecting system, makes this the most comprehensive of currently available diagnostic studies.

Rohrschneider et al prospectively evaluated 62 patients with static–dynamic MRU and compared the results with DRS for split function and urinary excretion, which served as the reference standard.[24] DRF, by MRU, was determined by comparing right vs left parenchymal uptake and volume, and dynamic sequences were used to generate whole kidney ROIs, which were used to assess urinary excretion. Urinary excretion was classified similarly by MRU and DRS in 81% of the abnormal kidney–ureter units and in 100% of normal kidney units. Interestingly, in their study, MRU tended to overestimate the severity of obstruction compared with DRS. However, MRU never indicated sufficient urinary drainage when DRS indicated relevant obstruction. The higher sensitivity of Gd-MRU compared with DRS explains this finding.

One study, by Chu et al, offers limited evidence that Gd-MRU may also be more specific in the prognostication of renal deterioration than DRS.[22] In this study, 8 children with unilateral hydronephrosis were evaluated by both MRU and DRS. DRS showed drainage in 3 hydronephrotic kidneys and poor washout in 5. By contrast, Gd-MRU showed drainage in all but 1 of these patients. Four of the 5 hydronephrotic units labeled as obstructed on DRS, but that had drainage by MRU, had no evidence of worsening hydronephrosis or functional deterioration at a mean follow-up of 18 months. Furthermore, antegrade pyelography performed on 2 of these patients who were classified as obstructed by DRS, but not on MRU, showed no evidence of high-grade UPJO. The 1 patient with an obstructive pattern by both MRU and DRS was confirmed to have significant UPJO on antegrade pyelography, and this patient subsequently underwent dismembered pyeloplasty. In a prospective study at Children's Healthcare of Atlanta comparing US, DRS, and MRU in the evaluation of hydronephrosis, MRU provided equivalent information about renal function but superior information regarding morphology in a single study without ionizing radiation.[27] Gd-MRU has also been shown to have a higher sensitivity (100% vs 96%), positive predictive value (86% vs 76%), negative predictive value (100% vs 90%), and diagnostic efficiency (90% vs 79%) than DRS.[23]

At Children's Healthcare of Atlanta, we have used Gd-MRU to evaluate over 300 children with hydronephrosis. MRU has been found to be particularly useful for diagnosis and evaluation of a wide range of renal obstructive anomalies, including UPJO, megaureter, and ectopic ureters (Figure 28.10) and currently the technique is also used to evaluate surgical results in patients pre- and postoperatively. For example, kidneys following pyeloplasty have shown statistically significant improvements in GFR (Patlak), corticomedullary transit and renal transit times, and degree of hydronephrosis following dismembered pyeloplasty.[28] MRU has a sensitivity comparable with ^{99m}Tc DMSA renal scintigraphy for the detection of renal scars and has been combined with MR voiding cystourethrography to diagnose VUR.[25] Indeed, the availability of MRU has influenced our diagnostic strategy for the evaluation of

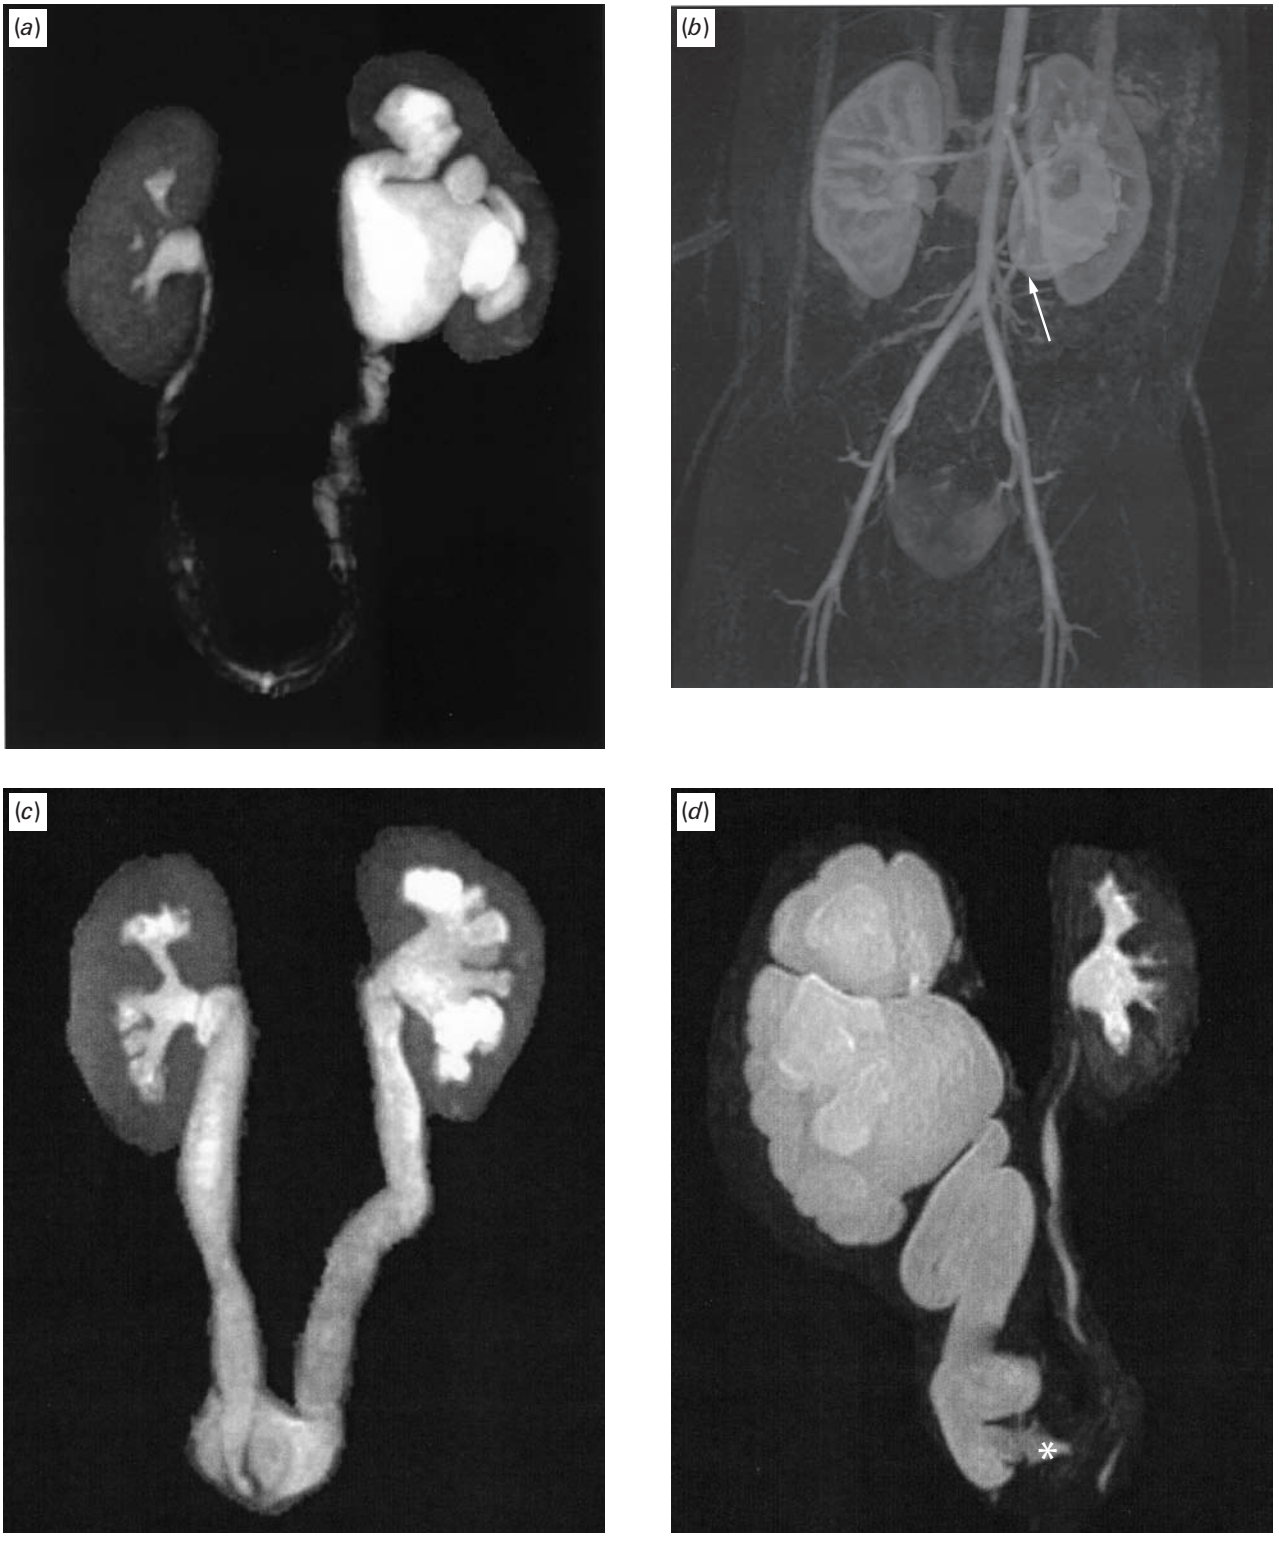

Figure 28.10 (*a*) A 6-year-old patient with left UPJO as seen by MRU. (*b*) On color enhanced images, a crossing vessel can be appreciated (arrow). (*c*) A 5-year-old child with bilateral non-obstructing megaureter. (*d*) A 9-year-old child with a right ectopic ureter, inserting below the bladder neck (asterisk), causing severe hydroureteronephrosis.

pediatric hydronephrosis. We have adapted our diagnostic algorithm to include MRU and currently use this modality in evaluation of most patients with SFU grades III and IV hydronephrosis on confirmatory sonography (Figure 28.11). Indications for surgical intervention based on Gd-MRU are more rigorous than DRS and include:

- DRF of <35–40%
- RTT of >8 minutes
- prolonged CMC times
- decreasing GFR, as indicated by the Patlak index
- anatomic findings

As for DRS, surgical decisions should not be based on isolated MRU criteria.

Despite the advantages of MRU, there are obstacles to its widespread acceptance. First, standardized equations and values used to determine function and classify drainage have not yet been wholly agreed upon. Larger studies with longer-term follow-up are still needed. Secondly, sedation is required for most children. Although techniques using phenobarbital or chloral hydrate have been shown to be safe, patients must be monitored throughout the study with oxygen saturation monitors. Lastly, there are increased costs associated with MRU and availability remains limited. Although MRU is currently more costly than renal scintigraphy, the comprehensive information obtained may justify its use, especially since it does not use ionizing radiation, and companion studies (e.g. retrograde urography), are no longer needed. Furthermore, cost and availability issues are likely to become less important in the future as use of this modality continues to increase. Indeed, over the next several years it is likely that MRU will replace renal scintigraphy in the evaluation of the pediatric urinary tract.

Conclusions

The accurate diagnosis and assessment of pediatric renal obstructive disorders is a principal task in pediatric urology. As a result of ongoing technologic advances, the diagnostic armamentarium available to clinicians for accomplishing this task has increased

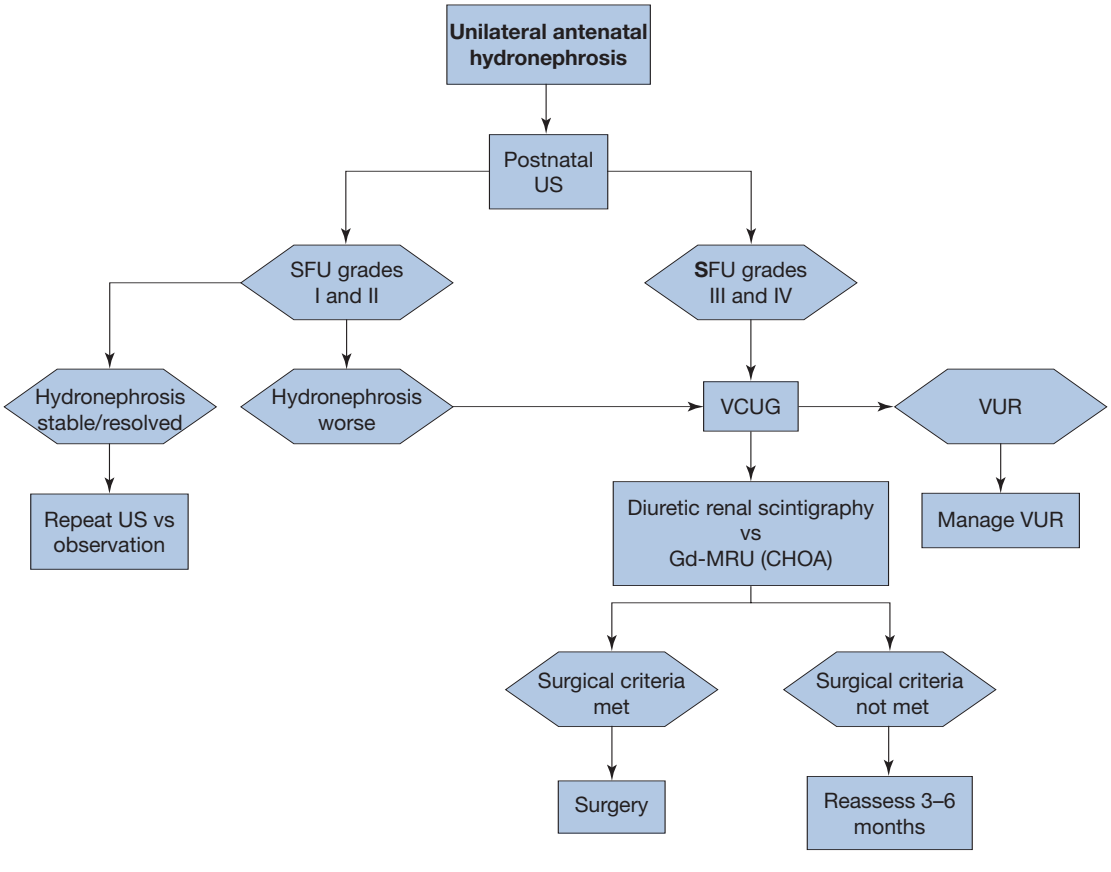

Figure 28.11 Algorithm for the evaluation of antenatal hydronephrosis. At Children's Healthcare of Atlanta (CHOA), gadolinium-enhanced MRU is used in preference to diuretic renal scintigraphy.

dramatically. Nevertheless, a series of radiologic studies, consisting of US, DRS, and VCUG, are still typically used to comprehensively evaluate many children. MRU has the potential to become a gold standard in the evaluation of these children. This single study, which does not require ionizing radiation, provides superior anatomic detail and, arguably, more accurate renal functional information than any other combination of studies. Cost and availability issues remain future challenges and may be the only factors preventing MRU from completely replacing renal scintigraphy.

Assessment of renal obstructive disorders: urodynamics of the upper tract

29

Leo CT Fung* and Yegappan Lakshmanan

Introduction

Clinical presentation

Routine use of prenatal ultrasonography has resulted in the diagnosis of large numbers of fetuses with hydronephrosis, which occurs in approximately 1 in 800 pregnancies. Some of these asymptomatic congenitally hydronephrotic kidneys improve spontaneously, whereas others progressively deteriorate unless the obstruction is relieved. Clinical parameters used to evaluate hydronephrosis are not always helpful in differentiating between the two groups. The pediatric urologist is charged with the responsibility of distinguishing between ongoing significant obstruction and innocuous residual dilatation of the collecting system in order to institute the appropriate clinical management.

The distinction between true obstruction and mere residual dilatation can be challenging. Anatomic evaluation alone, by ultrasonography and other radiologic imaging, accurately delineates the degree of dilatation, but is insufficient to determine the degree of obstruction. Nuclear medicine renal scans provide functional information in the evaluation of hydronephrosis, but there is a lack of consensus in how these parameters should be used to guide management. In the absence of clear indications of obstruction or lack thereof, clinical decisions are usually based on serial assessments of the hydronephrotic, and possibly obstructed renal unit. The inherent risk in this approach is the possible loss of renal function, which may be sudden and irreversible, if surgical correction of the obstruction fails to be instituted before the loss of renal function occurs.

In situations where surgical intervention is clearly indicated, or if the risk of functional deterioration is minimal, the use of upper tract urodynamic studies is not necessary. When routine tests are insufficient, or unable to clarify the diagnosis, however, upper tract urodynamic studies can provide invaluable diagnostic information.

Role of upper tract urodynamics

Although hydronephrosis is a highly complex physiologic process, the source of the problem is essentially physical in nature. In any biologic fluid conduit system, the resistance of the conduit is directly proportional to pressure over flow (resistance ∞ pressure/flow), modified from the Poiseuille–Hagen law,[1] which was originally applied to the flow of Newtonian fluids through rigid tubes. Based on this principle, both pressure and flow must be taken into account simultaneously in order to derive a measurement of the resistance within the conduit. Without taking both pressure and flow parameters into account simultaneously, as is the case in ultrasonography and other purely image-based modalities, or in nuclear renography, results cannot be used to draw conclusions regarding the resistance within the collecting system. In contrast, upper tract urodynamics are designed to take into account both the pressure within the collecting system and the rate of fluid flow; hence the synonymous term percutaneous pressure–flow studies. Upper tract urodynamic studies are intrinsically different from imaging studies and nuclear renal scans in that they provide a measure of the resistance of the collecting system, which is fundamental in the evaluation of hydronephrosis and in the diagnosis of obstruction.

Percutaneous pressure–flow study

In performing pressure–flow studies in the assessment of upper tract urodynamics, direct access to the prox-

imal collecting system is necessary to measure the fluid pressure within the system (Figure 29.1). Insertion of two 22 gauge 2 inch angiocatheters under sonographic guidance and fluoroscopic monitoring has been found to be effective and safe in our experience (Figure 29.2). In children the study can be carried out under either heavy sedation or general anesthesia.

In performing upper tract urodynamic studies, or pressure–flow studies, as the name implies, there is a pressure component, and there is also a flow component. One therefore needs to establish what constitutes normal as opposed to abnormally elevated renal pelvic pressures. Secondly, one also needs to determine what constitutes appropriate flow rates that would optimally challenge the collecting system within physiologic limits. These considerations will now be described in turn.

Threshold for normal renal pelvic pressure

A number of experimental and clinical studies have attempted to define the upper limit of normal collecting system pressure. In the rat model, the proximal renal tubular pressure, intratubular and peritubular capillary pressures all remain constant until the collecting system pressure exceeds normal renal tubular pressure. In the rat, the normal proximal renal tubu-

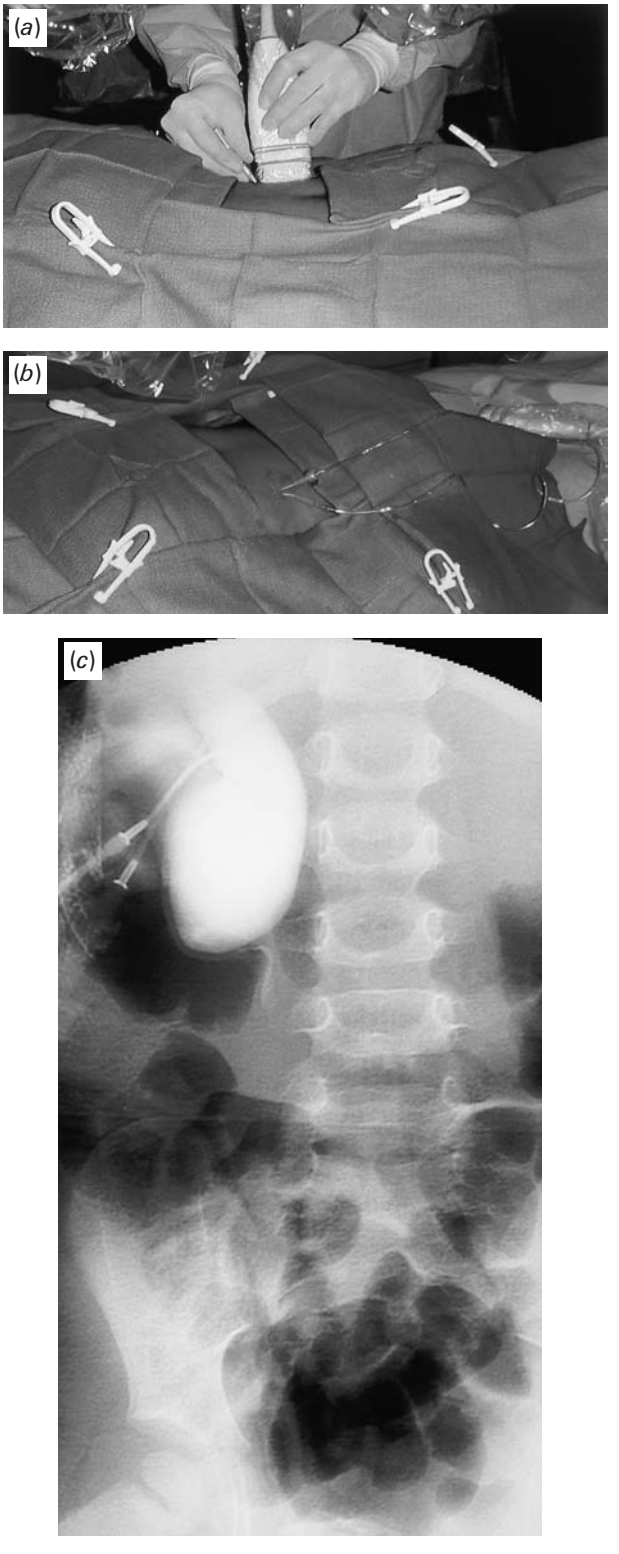

Figure 29.2 For the percutaneous pressure–flow studies performed in children at the authors' institution, all studies are performed under general anesthesia in the prone position. (*a*) and (*b*) Two 22 gauge angiocatheters are inserted into the collecting system percutaneously under ultrasonographic guidance. Infusion of contrast verifies satisfactory nephrostomy access. (*c*) Antegrade nephrostogram in prone position.

lar pressure was established to be 14.1 ± 0.5 cmH_2O.[3] In the human, intrarenal arterial resistance increases acutely once the renal pelvic pressure rises above 14 cmH_2O.[4] Furthermore, Fichtner et al showed that in the congenitally hydronephrotic rat model, mean renal pelvic pressure was 14.1 ± 1.6 cmH_2O under very high urine output with an empty bladder.[5] The mean renal pelvic pressure increased further when the bladder was filled. In contrast, mean renal pelvic pressure in normal controls was below 14 cmH_2O under high urine output. Even with the bladder filled to capacity, the highest mean renal pelvic pressure recorded was only 13.2 ± 1.6 cmH_2O. These studies suggest that the upper limit of normal renal pelvic pressure is 14 cmH_2O, above which undesirable physiologic changes begin to occur.

Additional evidence indicates that continuous elevation in renal pelvic pressure leads to acute and irreversible renal injury within 24 hours. In a porcine model of constantly elevated renal pelvic pressure between 20 and 40 cmH_2O, the urinary level of *N*-acetyl-β-D-glucosaminidase (NAG) was found to be elevated, which is indicative of acute tubular cell membrane disruption.[6] Similar conditions also resulted in acute onset of apoptotic cell death, signifying irreversible injury.[7] These changes were associated with decreased renal blood flow, and up-regulated vascular endothelial growth factor (VEGF) mRNA levels, suggesting that decreased perfusion and tissue hypoxia play an important role when renal pelvic pressure is elevated.[6] Renal injury was significantly greater in the experimental group, with renal pelvic pressure ranging from 20 to 40 cmH_2O, compared with the control animals with renal pelvic pressure of 10 cmH_2O or less. Based on these results, the threshold for physiogically safe renal pelvic pressure seems to lie somewhere between 10 and 20 cmH_2O. Although the precise pressure threshold above which renal injury occurs remains undefined, these experiments are consistent with 14 cmH_2O as the upper limit of normal renal pelvic pressure, as established previously in both rat and human studies.

Optimal flow challenge to the collecting system

The normal renal collecting system handles a wide range of urinary flow rates, as urine output varies under a variety of normal physiologic conditions. A normal collecting system should be able to handle this normal range of flow rates without an undue rise in pressure. In an 'obstructed' collecting system, on the other hand, there is an abnormally high resistance, causing elevated pressures whenever the flow rate exceeds its limited capacity for fluid transport. The increase in pressure in an obstructed collecting system is directly proportional to the rate of flow and the degree of obstruction, according to the modified Poiseuille–Hagen law.[1] However, if the collecting system is presented with a flow challenge that is excessively high and unphysiologic, even normal collecting systems may potentially be overwhelmed and develop elevations in pressure beyond the physiologically normal limit. In performing upper tract urodynamic studies, the flow rate chosen to optimally challenge the collecting system should therefore reflect the maximum urine output that the kidney is capable of generating under normal physiologic conditions.

Individualized infusion pressure–flow study

The pioneering work in infusion pressure–flow studies was carried out by Whitaker,[8] and the initial form of pressure–flow study is referred to as the Whitaker test. Whitaker advocated using a standard external infusion rate of 10 ml/min, with lower infusion rates of 2–5 ml/min for smaller children. An even higher infusion rate of 15 ml/min can be used in adults for a more stringent flow challenge. Intrapelvic pressures <10 cmH_2O were interpreted as normal. Pressures >20 cmH_2O were abnormal and those between 10 and 20 cmH_2O were considered indeterminate. Although these concepts were sound in principle, there was no specific guideline to determine what infusion rate should be used for children of a given age and body size. Further work was therefore undertaken by Fung et al in an attempt to clarify the infusion rates used, to provide physiologically meaningful results.[9] Three patient parameters form the basis for the calculated estimate of the patient's maximum physiologic urine output:

- body surface area
- age-adjusted 90th percentile glomerular filtration rate (GFR)
- the maximum percentage of the GFR one can physiologically excrete as urine.

Both surface area[10] and 90th percentile GFR (ml/min/1.73 m^2) for the patient's age (Figure 29.3)[11] can be obtained from population nomograms. Since the renal tubules proximal to the segment sensitive to antidiuretic hormone reclaim about

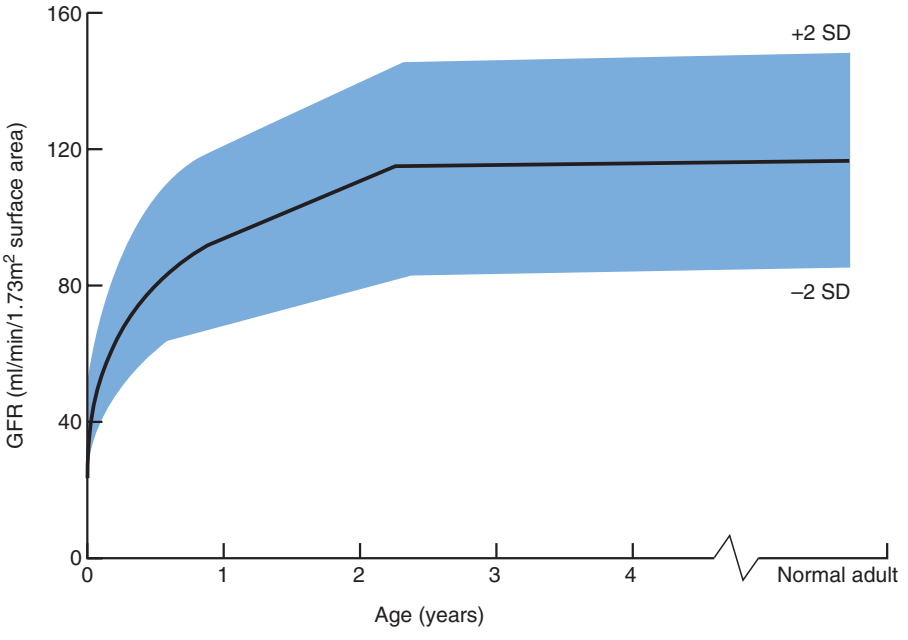

Figure 29.3 Age-adjusted glomerular filtration rate (GFR, in ml/min per 1.73 m^2) nomogram. (Adapted from McCrory.[11])

80% of the water in the glomerular ultrafiltrate, under non-pathologic conditions the maximum physiologic diuresis cannot exceed approximately 20% of the GFR, even in the complete absence of antidiuretic hormone.[12] The calculation can be summarized as:

$$\text{maximum physiologic urine output per kidney (ml/min)} = \frac{\text{surface area } (m^2) \times \text{age-adjusted GFR (ml/min/1.73 } m^2) \times 20\% \text{ of total GFR}}{1.73\ m^2 \times \text{number of kidneys}}$$

Since the pressure–flow study is applied to one kidney at a time, the flow rate employed is based on the maximum physiologic urine output per kidney: hence the correction factor 'number of kidneys'. For patients who have a solitary kidney, compensatory hypertrophy and hyperplasia need to be taken into account. This formula is directly applicable only if the GFR of the solitary kidney has compensated to a level similar to the population-normal total GFR.

For a patient whose total GFR and differential renal function are known, maximum physiologic urine output can be derived directly with this formula. Maximum physiologic urine output for the kidney of interest would then be 20% of the measured total GFR (ml/min) multiplied by the differential renal function for that kidney (%):

$$\text{maximum physiologic urine output per kidney (ml/min)} = \text{measured total GFR (ml/min)} \times 20\% \text{ of total GFR} \times \text{differential renal function (\%)}$$

When these calculations were performed for patients of different ages and body sizes, the appropriate infusion rate corresponding to the respective maximum physiologic urine output per kidney ranged from 0.85 ml/min (appropriate for a 4-week-old infant) to 16.31 ml/min (appropriate for a large ≥18-year-old patient) (Table 29.1). This tremendously wide range underscores the importance of individualizing the infusion rate used for each pediatric patient.[9]

As previously noted, a non-obstructed system should maintain a peak renal pelvic pressure no higher than the upper limit of normal physiologically – i.e. maintain a peak renal pelvic pressure of ≤14 cmH_2O. By contrast, a collecting system with significant obstruction can be expected to develop a peak renal pelvic pressure of >14 cmH_2O. If the renal pelvic pressure remains well below 14 cmH_2O at the individualized infusion rate, one can arbitrarily increase the infusion rate by 50% or 100% to challenge the collecting system drainage with a supraphysiologic flow rate to test the reserve capability of that collecting system. However, an elevated renal pelvic pressure (>14 cmH_2O) in this setting is not necessarily

Table 29.1 Height, weight, and glomerular filtration rate (GFR) values are obtained from population nomograms[a]

Age (years)	Height (cm)		Weight (kg)		Surface area (m^2)		GFR 90th percentile (ml/min/ 1.73 m^2)	Maximum physiologic urine output per kidney (ml/min)

[a] The calculated physiologically maximum urine outputs are provided as rough guidelines for the individualized pressure–flow study infusion rates.
Note: The maximum urine output estimates tabulated here are expressed as the infusion rate per kidney, representing half of the total calculated urine output estimate. For patients with a solitary kidney, the infusion rate may need to be increased in proportion to its compensatory increase in GFR.

indicative of significant obstruction, as the supraphysiologic infusion rate represents a flow rate that exceeds the urine output from the kidney under physiologic conditions; instead, it would be an indication that the collecting system being tested is borderline for a significant degree of obstruction, with little additional reserve capacity for handling higher urinary flow rates.

These modifications from Whitaker's original descriptions form the basis for the individualized infusion pressure–flow study. It is important to note that a urethral catheter is routinely used to keep the bladder empty during all pressure–flow studies to minimize the potential of renal pelvic pressure readings being artificially affected by a full bladder.

Diuresis pressure–flow study

Individualized adjusted infusion rates, as described in the individualized infusion pressure–flow study, help to ensure that the collecting systems being tested are challenged with appropriately infused flow rates. However, externally infused flow rates are, after all, from an extracorporeal source and are not physiologic. In order to render the flow challenge in upper tract urodynamics more physiologic, it is possible to eliminate the need for an external infusion during the pressure–flow study, and instead challenge the collecting system with a diuresis induced by pharmacologic means, such as the intravenous administration of furosemide.[13] Nephrostomy access is still necessary to measure renal pelvic pressure, as is urethral catheterization. Instead of an external infusion, the patient receives an intravenous bolus of 15 ml/kg of a crystalloid solution followed by 1 mg/kg of intravenous furosemide up to a maximum of 10 mg. Renal pelvic pressure is continuously monitored for 30 minutes after the furosemide administration (Figure 29.4), and urine output monitored every 5–10 minutes to ensure that an adequate diuresis has been induced. Similar to the individualized infusion pressure–flow study, a peak renal pelvic pressure of ≤14 cmH_2O is considered normal whereas a peak renal pelvic pressure of >14 cmH_2O is considered obstructed.

In a series of over 55 patients who received both the individualized infusion and the diuresis pressure–flow studies, peak renal pelvic pressures obtained from the two pressure–flow studies were found to be similar, agreeing in all but three cases. In these three patients, test results were either borderline positive or borderline negative, with the peak renal pelvic pressures differing by only 2–3 cmH_2O.[13]

The diuresis pressure–flow study differs from the individualized infusion pressure–flow study in more ways than just how the flow challenge to the collecting system is generated. The externally infused flow of an individualized infusion study challenges the collecting system, but cannot measure how the kidney may have responded to the obstruction present in the collecting system. Based on our current understanding of how the kidney responds to obstruction, however, the diuretic pressure–flow study not only provides information on the resistance present in the collecting system but also may help uncover compensatory physiologic changes present in kidneys in response to physiologically significant obstruction.

Based on our current understanding of renal obstruction, the collecting system pressure of a chronically obstructed kidney remains within the normal range.[14] In these obstructed kidneys, the normal collecting system pressure is a result of long-term compensatory changes occurring in the kidney, with reductions in renal blood flow and GFR proportional to the degree of outflow obstruction. In terms of the collecting system pressure at baseline conditions, a hydronephrotic kidney with a significantly obstructed collecting system is therefore indistinguishable from a non-obstructed kidney. However, the hydronephrotic kidney with ongoing significant obstruction maintains normal renal pelvic pressure because of a state of equilibrium from changes in renal blood flow and GFR compensating for the outflow obstruction.[14] In this compensated state of equilibrium, the renal blood flow and GFR decrease in the obstructed kidney just enough to compensate for the existing outflow obstruction at baseline conditions, and the collecting system has little or no reserve for handling any increase in urine flow. If such a kidney were to be challenged with a furosemide-induced diuresis, it is logical that an elevation in renal pelvic pressure would ensue. In a non-obstructed collecting system, by contrast, experimental animal studies have documented a significant reserve capacity for handling diuresis beyond baseline urine output, while maintaining renal pelvic pressures below the upper limit of normal.[5]

Furosemide-induced diuresis is therefore more than just a flow challenge to the collecting system; it is, in fact, also a means of 'agitating' the equilibrium established in the renal blood flow, GFR, and collecting system pressure of significantly obstructed kidneys. Thus, a positive diuresis pressure–flow study (peak renal pelvic pressure >14 cmH_2O) indicates not only a collecting system with an abnormally high resistance

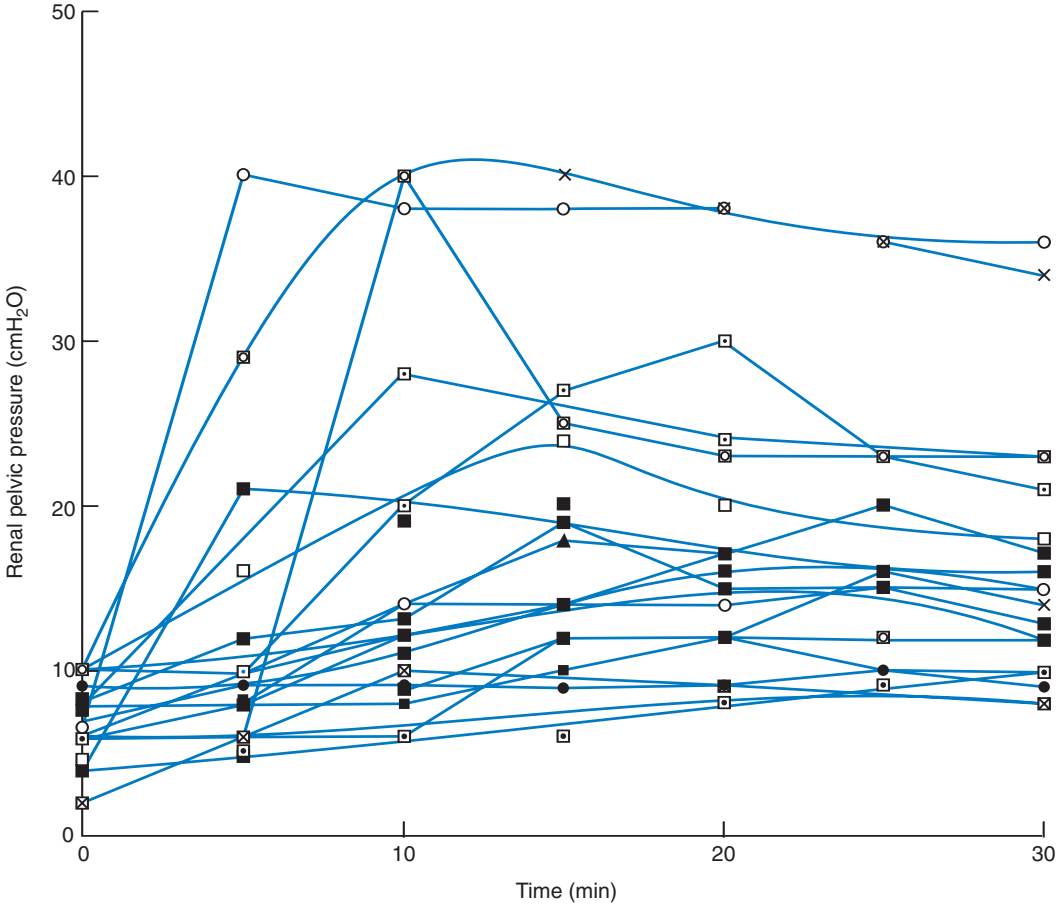

Figure 29.4 Composite graph of a representative group of patients with hydronephrosis undergoing diuresis pressure–flow studies, where renal pelvic pressure is plotted against time. Renal pelvic pressure at time 0 represents baseline pressure. Intravenous furosemide, 1 mg/kg, up to a maximum of 10 mg, was given at time 0, and renal pelvic pressure was monitored for 30 minutes. The furosemide-induced diuresis consitutes the sole form of fluid challenge, and no infusion of fluid takes place during these studies. In the authors' experience studying over 55 hydronephrotic kidneys to date (data not all plotted in this graph in order to maintain clarity), it has been consistently observed that the prediuresis baseline renal pelvic pressures remain relatively low, and do not exceed 10 cmH_2O. The highest renal pelvic pressure recorded to date is 63 cmH_2O, observed in a patient with ureteropelvic junction (UPJ) obstruction and no evidence of contrast draining across the UPJ throughout the entire pressure–flow study.

to flow but also that the kidney being tested is probably in a compensated state of equilibrium, precariously maintaining a normal renal pelvic pressure at baseline conditions at the expense of decreased renal blood flow and/or GFR.

In our current series of over 55 patients, positive studies correlate with those of patients who are symptomatic or show evidence of renal functional deterioration. These correlations suggest that a positive diuresis pressure–flow study is predictive of functionally significant obstruction. Conversely, those with negative diuresis pressure–flow studies have shown no evidence of deterioration or required surgical intervention for symptomatic complaints at a follow-up of 2 years (Figure 29.5).

Upper tract urodynamics and nuclear diuretic renography: similarities and differences

Because of the relatively invasive nature of establishing percutaneous nephrostomy access, it is important to clarify whether the pressure–flow studies reveal uniquely important diagnostic information as compared to the more commonly used diuretic renogram. The protocols for the diuresis pressure–flow study are similar to those for diuretic nuclear renography: both modalities share the use of a urethral catheter to keep the bladder empty, the infusion of an intravenous crystalloid solution to ensure adequate patient hydration, and the administration of 1 mg/kg of intra-

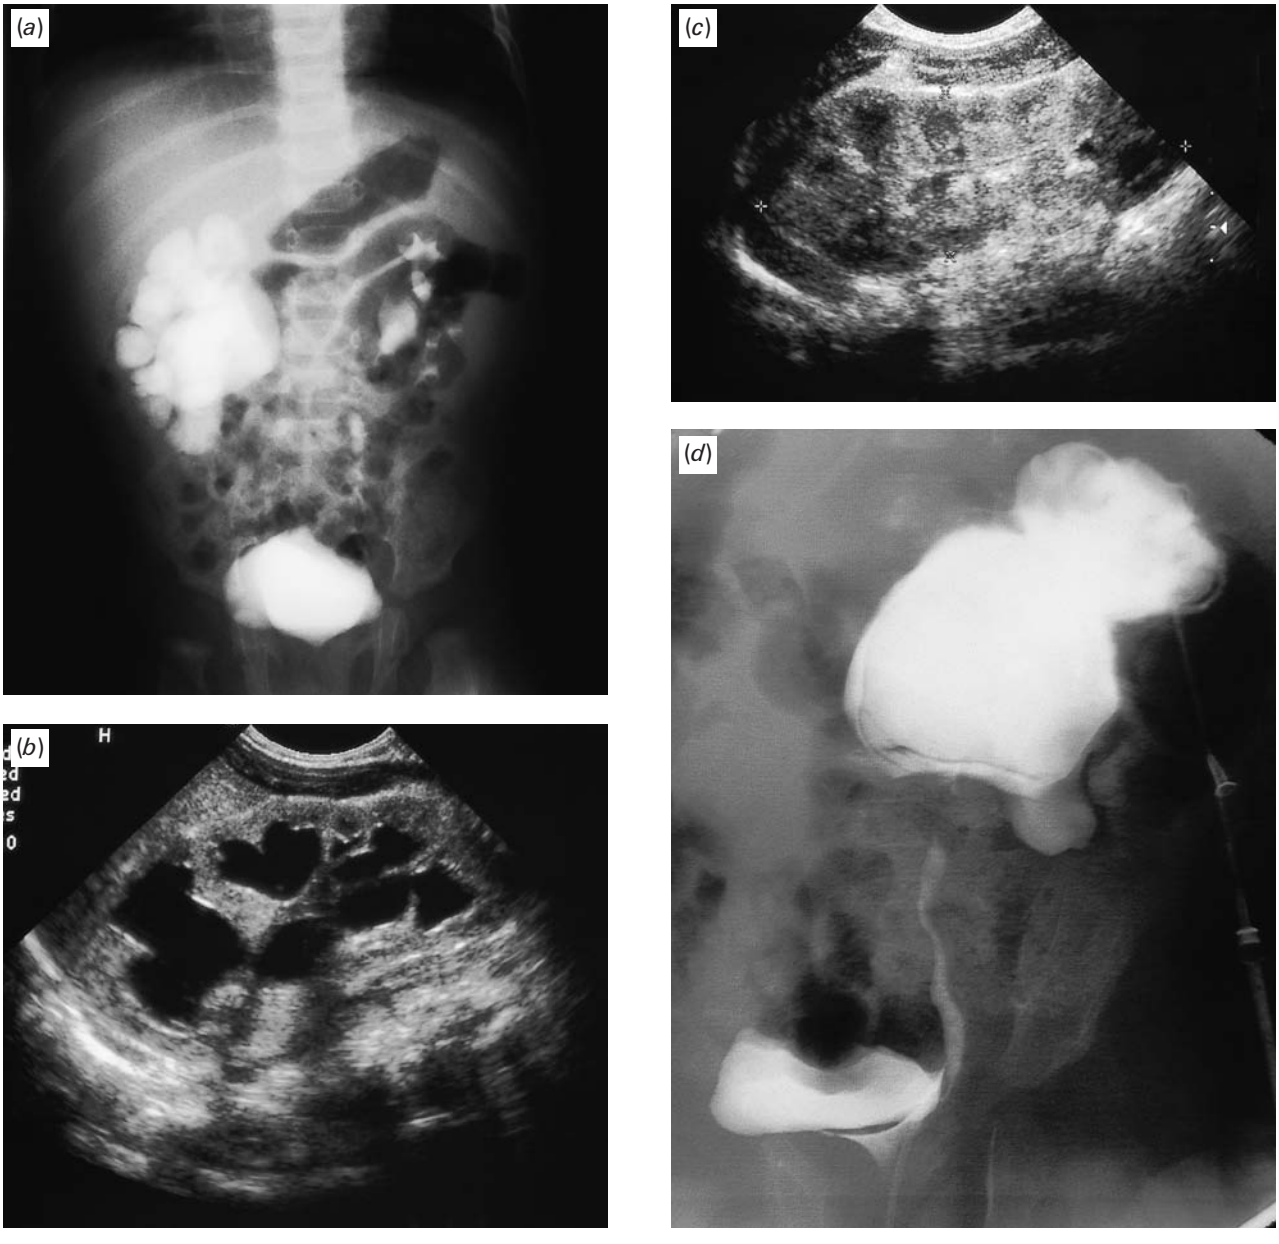

Figure 29.5 Male patient identified as having right hydronephrosis compatible with ureteropelvic junction (UPJ) obstruction, as shown by an intravenous pyelogram (*a*). Ultrasonography demonstrated marked right hydronephrosis with significant thinning of the renal cortex (*b*), and normal left kidney (*c*). A percutaneous pressure–flow study was performed when the patient was 7 weeks of age. (*d*) Right antegrade nephrostogram in the prone position. The pressure–flow study was negative for significant obstruction, where the peak renal pelvic pressure was only 5 cmH_2O, well below the upper limit of normal of 14 cmH_2O, under both furosemide-induced diuresis and a supraphysiologic infusion rate of 200%. Despite significant cortical thinning and pelvicaliectasis, the patient was managed with an observational approach in view of the negative pressure–flow study. From his initial right differential renal function of 30%, it spontaneously improved to 52% 1 year later, and further increased to 58% at his 2-year follow-up. It is unclear why his differential renal function increased to beyond 50%, but nevertheless the initial negative pressure–flow study appeared to be reliable in excluding significant UPJ obstruction.

venous furosemide to challenge the collecting system with a diuresis. However, the key parameters assessed by the two studies are fundamentally different: the diuresis pressure–flow study examines renal pelvic pressure changes as urine flow increases, whereas diuretic nuclear renography measures the washout $t_{1/2}$, a semiquantitative measure of the rate of flow of urine across the suspected site of obstruction. When

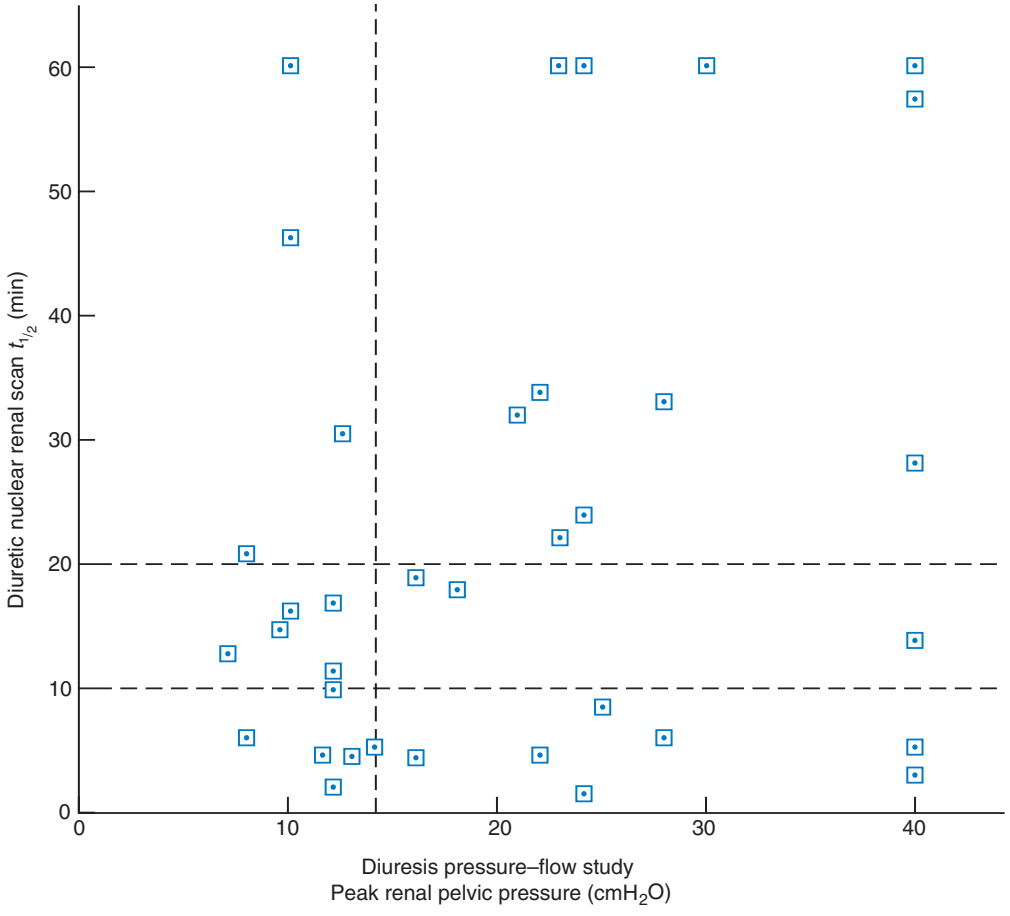

Figure 29.6 Correlation graph depicting diuretic nuclear renal scan $t_{1/2}$ against peak renal pelvic pressure recorded during diuresis pressure–flow studies. Whereas the basic protocols of the two forms of test appear similar, including similar intravenous hydration, furosemide administration, and the use of a bladder catheter, the results of the two tests have little correlation with each other, and these two variables are essentially independent of each other.

we studied 46 hydronephrotic kidneys with both the diuresis pressure–flow study and diuretic nuclear renography, it was found that renal pelvic pressure alterations had little correlation with the washout $t_{1/2}$, and that these two variables were essentially independent of each other (Figure 29.6). Some of the kidneys examined in this study showed evidence of significant obstruction, with markedly increased collecting system pressure on the diuresis pressure–flow study, yet the washout $t_{1/2}$ was normal. Conversely, some of the kidneys examined showed no evidence of significant obstruction, with normal renal pelvic pressure throughout, yet the washout $t_{1/2}$ was grossly elevated. A similar disparity between washout curve results and infusion pressure–flow study results was reported by Dacher et al;[15] however, those results that did not correlate were mostly from a specific group of postoperative patients with severely dilated collecting systems.

Resistance can be assessed only if both pressure and flow parameters are simultaneously taken into account. These differences observed between the washout $t_{1/2}$ and the diuresis pressure–flow study results support the concept that these parameters do not measure the same variables: namely, the washout $t_{1/2}$ provides a semiquantitative measure of flow across the suspected site of obstruction, whereas the pressure–flow study result reflects the resistance within the collecting system being tested. Further studies and long-term clinical follow-up will be required to clarify the clinical significance of these differences.

Fluoroscopic monitoring and ureteral opening pressure

At the beginning of a pressure–flow study, it is helpful to instill contrast into the renal pelvis to verify

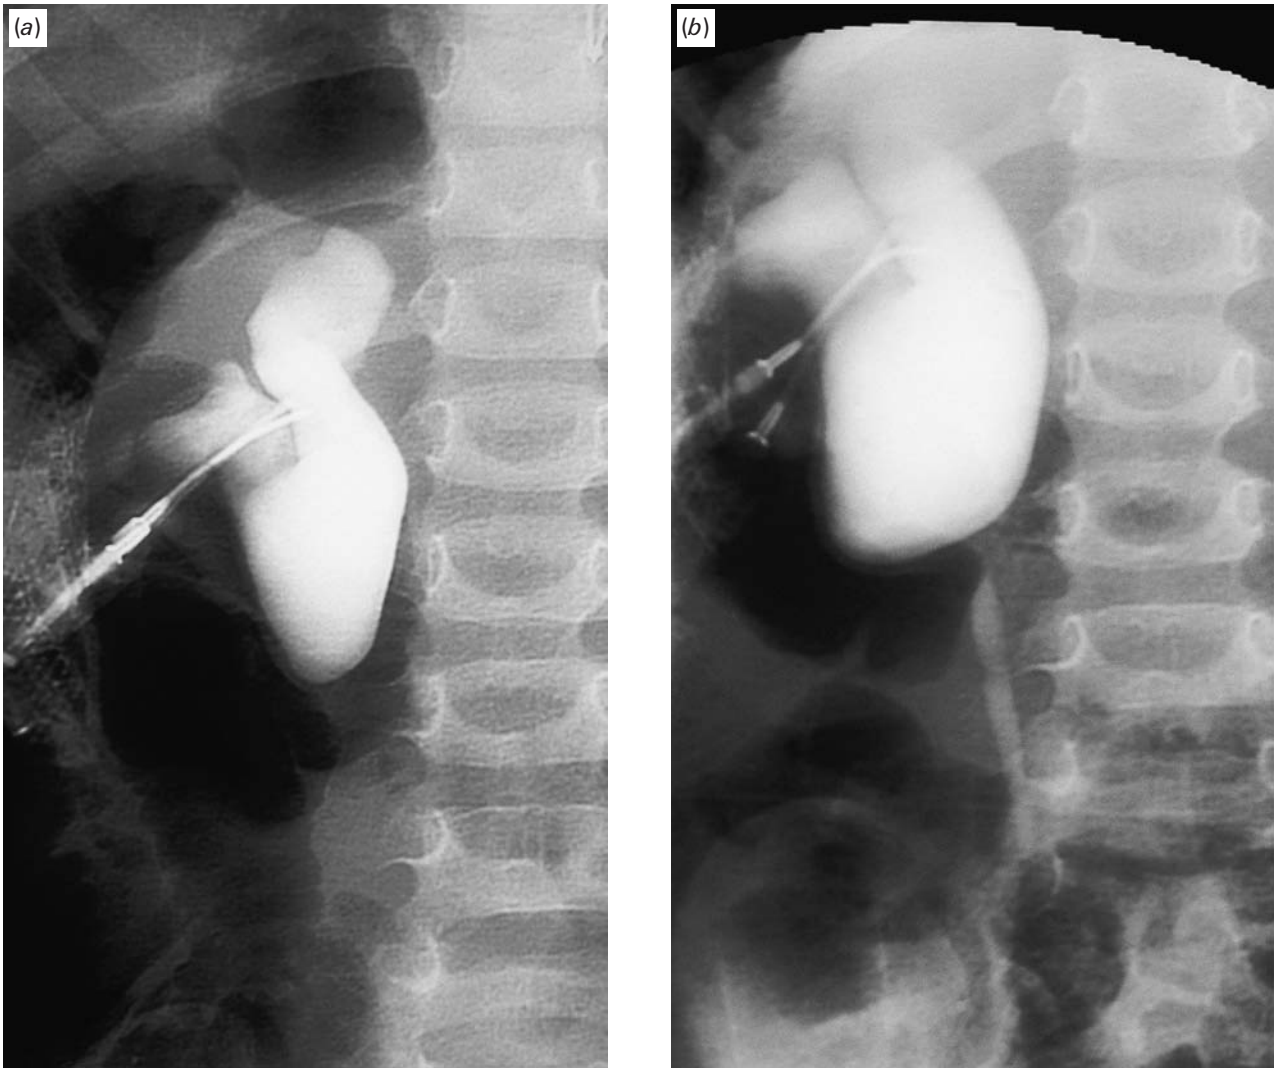

Figure 29.7 Ureteral opening pressure is defined as the pressure at which antegrade contrast is first seen distal to the suspected site of obstruction. In this 4-year-old boy with left hydronephrosis, no contrast was seen to enter the ureter ((*a*) left antegrade nephrostogram in the prone position) until his left renal pelvic pressure reached 17 cmH_2O (*b*). His ureteral opening pressure of 17 cmH_2O is compatible with significant ureteropelvic junction (UPJ) obstruction.

proper positioning of the nephrostomy access. Before the instillation of contrast, however, an equivalent volume of urine should first be aspirated out, so that the baseline pressure dynamics of the renal pelvis remain essentially unchanged. With contrast present in the renal pelvis, it has the added advantage that subsequent renal pelvic pressure changes can then be correlated with dynamic anatomic alterations seen by periodic fluoroscopic monitoring. For example, the pressure at which antegrade contrast is first seen distal to the suspected site of obstruction can be measured. This parameter is defined as the ureteral opening pressure[16] (Figure 29.7). In our study of 52 renal units in 43 patients, positive (obstructed) ureteral opening pressures (>14 cmH_2O) had a 100% association with a positive individualized infusion pressure–flow study. When the ureteral opening pressure was negative (<14 cmH_2O), however, it was predictive of a negative individualized infusion pressure–flow study in only 57%.[16]

Antegrade infusion of contrast media also delineates the anatomic site of obstruction, and defines the ureter distal to the site of obstruction, which is useful in surgical planning (Figure 29.8).

Finally, fluoroscopic monitoring may be helpful in assessing patients with intermittent obstruction secondary to kinking of the ureteropelvic junction (UPJ). On initial infusion, the drainage may be rela-

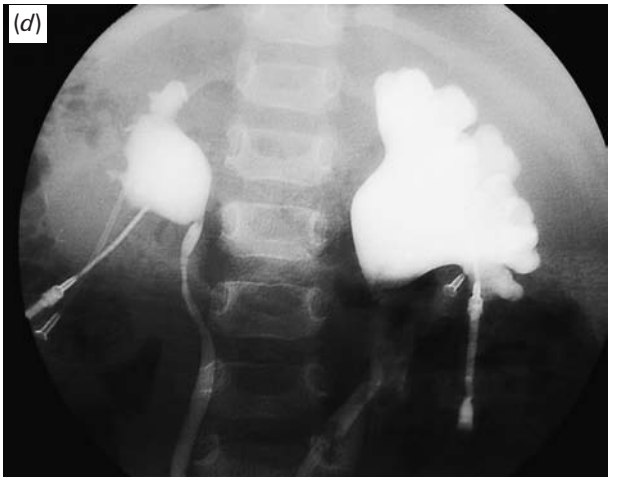

Figure 29.8 Antegrade infusion of contrast media can be an effective tool for delineating the anatomic site of obstruction. (*a*) In this 10-year-old girl, a partial ureteral duplication is well visualized with percutaneous nephrostomy access established to the lower moiety only. (*b*) Possible anomalies at the ureteropelvic junction (UPJ). (*c*) Possible anomalies at the UPJ, midureter, and ureterovesical can be seen in this 5.5-year-old boy with a history of posterior urethral valves. (*d*) Bilateral percutaneous pressure–flow studies can also be performed simultaneously.

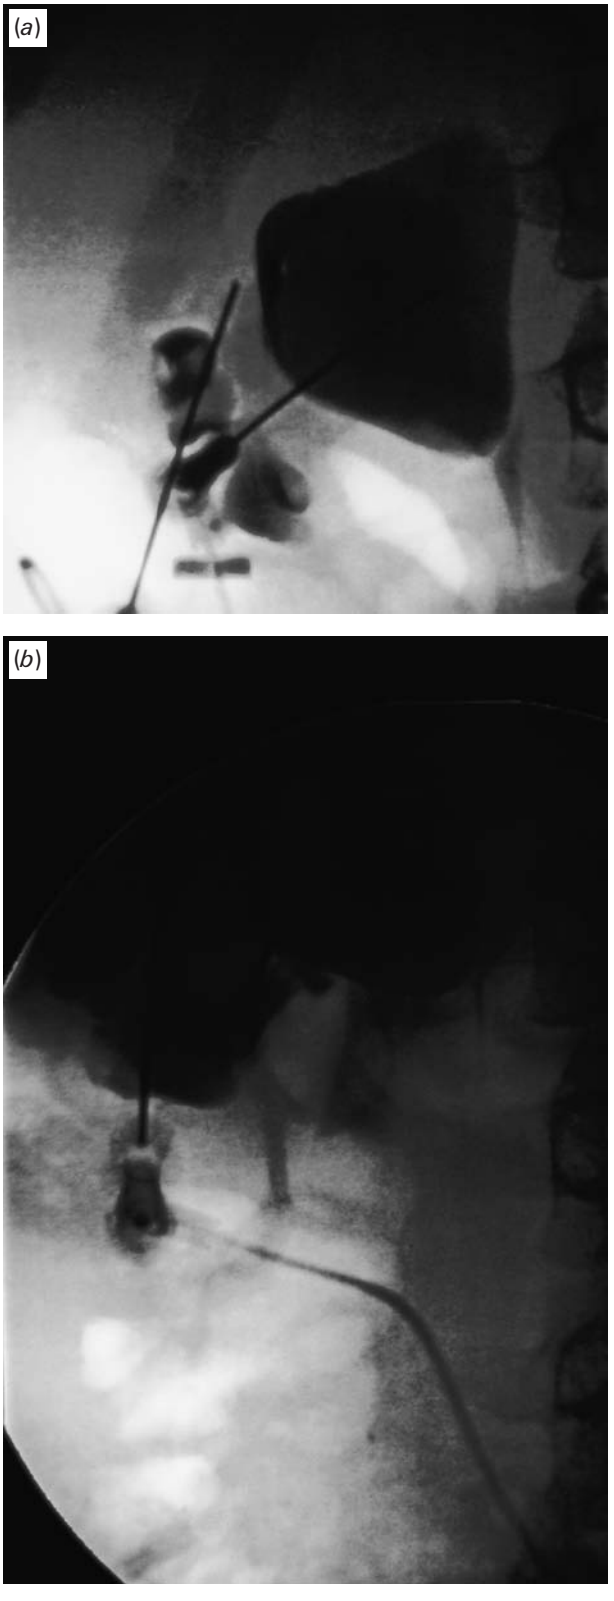

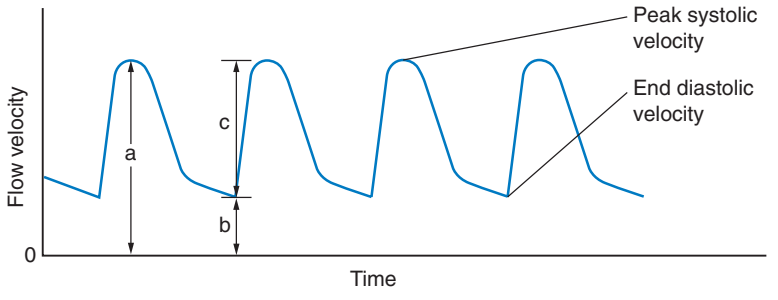

Figure 29.9 This 6-year-old girl was initially misdiagnosed as having chronic gastrointestinal disorder when she presented with recurrent abdominal pain, nausea, and vomiting. When she underwent a percutaneous pressure–flow study to evaluate her left hydronephrosis, contrast was seen to drain promptly across the ureteropelvic junction (UPJ) into the proximal ureter early in the study (*a*). As the renal pelvis became progressively more distended, the drainage of contrast across the UPJ ceased entirely (*b*). Renal pelvic pressure continued to rise sharply, and the pressure–flow study was terminated at 40 cmH_2O. No drainage of contrast was seen across the UPJ until fluid was aspirated out of the renal pelvis to decompress the grossly distended collecting system. When the renal pelvis dimensions returned towards their initial baseline, drainage across the UPJ resumed with a gush of contrast into the proximal ureter (*c*). This pattern of intermittent high-grade obstruction was presumed to be secondary to a kink at the UPJ that was accentuated by the renal pelvis becoming overdistended. Her recurrent abdominal pain, nausea, and vomiting episodes (Dietl's crisis) were successfully corrected by a dismembered pyeloplasty.

tively efficient. As the flow rate increases, however, the renal pelvis becomes increasingly dilated, progressively displacing the UPJ. In intermittently obstructing UPJs, this progressive dilation of the renal pelvis eventually causes the UPJ to kink, leading to an acute high-grade obstruction, with an ensuing progressive elevation in renal pelvic pressure. Little or no fluid moves through the UPJ. With cessation of infusion or

Table 29.2 Current percutaneous pressure–flow study protocol at University of Minnesota, Minneapolis, MN

- Patient is placed under general anesthesia with endotracheal intubation.
- With intravenous access established, antibiotic prophylaxis is given using 40 mg/kg of intravenous (i.v.) cefazolin up to a maximum of 1 g, provided that there is no history of allergic reaction, and hydration is begun with a minimum of 15 ml/kg of a crystalloid solution.
- In supine position, bladder catheter is inserted with the largest caliber catheter that the patient can accept.
- To facilitate placement of percutaneous nephrostomy needles, the bladder catheter may be plugged off at this stage to keep the bladder full and to maximize renal pelvic dilatation.
- The patient is turned to the prone position, and ultrasonographic examination is carried out to plan for nephrostomy access.
- The patient is sterilely prepared and draped. Under ultrasonographic guidance, two 22-gauge 2-inch angiocatheters (or other suitable catheters or needles) are inserted percutaneously into the renal pelvis to be examined. The bladder is emptied and the bladder catheter is connected to gravity drainage.
- To verify placement of the nephrostomy access and to establish a means to follow the progress of urine flow, radiographic contrast is injected into the renal pelvis via nephrostomy access. To preserve the baseline renal pelvic pressure dynamics, an equal volume of urine is first aspirated out before the injection of contrast.
- One of the nephrostomy accesses is capped off, and the other is connected to a pressure transducer with no flow going through the nephrostomy.
- The pressure transducer line is zeroed externally to the same level as the tip of the nephrostomy access within the renal pelvis. When connected to the nephrostomy access, the initial pressure reading represents the baseline renal pelvic pressure.
- Furosemide (1 mg/kg i.v., up to a maximum of 10 mg) is given to begin the *diuresis pressure–flow study* component.
- Renal pelvic pressure is continuously monitored for 30 minutes. Urine output is measured every 5 minutes to verify satisfactory overall response to i.v. hydration and furosemide. The peak renal pelvic pressure observed in this period determines whether the diuresis pressure–flow study is positive (peak renal pelvic pressure >14 cmH_2O) for significant obstruction.
- During this 30-minute interval, fluoroscopy is used intermittently. The renal pelvic pressure at which radiographic contrast is first seen distal to the suspected level of obstruction constitutes the *ureteral opening pressure*.
- If the diuresis pressure–flow study component is strongly positive for significant obstruction (peak renal pelvic pressure markedly above 14 cmH_2O), an antegrade nephrostogram is performed to obtain the anatomic details necessary for guiding surgical repair, and the percutaneous pressure–flow study is concluded at this point.
- If the diuresis pressure–flow study component peak renal pelvic pressure is close to or below 14 cmH_2O, the *individualized infusion pressure–flow study* is performed next. The other capped-off nephrostomy access is connected to an infusion pump, infusing a radiographic contrast solution. The rate of infusion is individually calculated based on patient's age, weight, and height (see Table 29.1) or calculated based on the GFR of the kidney being tested, if known.
- If the resulting renal pelvic pressure is positive for significant obstruction (>14 cmH_2O), an antegrade nephrostogram is performed to obtain the anatomic details necessary for guiding surgical repair, and the percutaneous pressure–flow study is concluded at this point.
- If the resulting renal pelvic pressure is negative for significant obstruction (≤ 14 cmH_2O), a supraphysiologic rate of infusion is then used (150–200% of the individualized infusion rate) as a measure of the reserve capability of the collecting system to handle additional urine flow.
  Note: Regardless of whether the renal pelvic pressure rises above 14 cmH_2O at this point, the pressure–flow study is still considered negative for significant obstruction.
- If a lower tract abnormality, which causes excessively high intravesical pressure, coexists with the upper tract obstructive site, an initially negative study for significant obstruction (diuresis pressure–flow study) can be further challenged with the bladder filled to the peak naturally occurring intravesical pressure. This is carried out by connecting an i.v. solution drip to the bladder catheter, and the drip chamber is raised to a level that is the same height (in cm) as the peak intravesical pressure (in cmH_2O). The desired intravesical pressure being simulated is reached when the drip slows to intermittent drops or stops altogether. The peak renal pelvic pressure recorded in this setting represents a combined effect of both the upper tract obstructive site and the lower tract anomaly on their corresponding upper tract urodynamics.
- Once all necessary urodynamic measurements have been completed, an antegrade nephrostogram is performed to obtain anatomic details necessary for guiding surgical repair. The renal pelvis is aspirated empty and the nephrostomy accesses are removed. The patient is turned back to supine position and awakened from anesthesia. The bladder catheter is removed once significant gross hematuria has been ruled out, and the patient is sufficiently awake to void.
- All patients who have percutaneous pressure–flow studies positive for significant obstruction are covered with oral antibiotic prophylaxis until successful surgical repairs have been achieved.

$$\text{Resistive index} = \frac{(\text{Peak systolic velocity} - \text{End diastolic velocity})}{\text{Peak systolic velocity}} \times 100\%$$

$$= \frac{a - b}{a} \times 100\%$$

$$= \frac{c}{a} \times 100\%$$

Figure 29.10 Schematic depiction of a typical intrarenal arterial waveform. Parameters and formula used for calculating intrarenal resistive index (RI) are shown. (After Fung et al.[4])

diuresis, the process eventually reverses itself. This may require drainage from the renal pelvic nephrostomy to speed up the decompression process. When intrapelvic volume reaches approximately the threshold at which the UPJ kinking initially occurred, the UPJ can be seen to suddenly open and renal pelvic pressure rapidly returns to normal thereafter (Figure 29.9).

Our current percutaneous pressure–flow study protocol, which represents our effort in combining the strengths of the various components of a pressure–flow study as discussed above, is presented in Table 29.2.

Diuretic Doppler sonography and intrarenal resistive index

The invasive nature of obtaining percutaneous access to the renal pelvis is one of the key factors preventing upper tract urodynamic studies from being performed on a more routine basis as part of the evaluation of hydronephrosis. Thus, it would be desirable to have a non-invasive method measuring parameters which reflect the collecting system pressure elevations in significantly obstructed renal units. The diuretic Doppler sonography study has the potential for being such a non-invasive study that is useful in upper tract urodynamic evaluations.

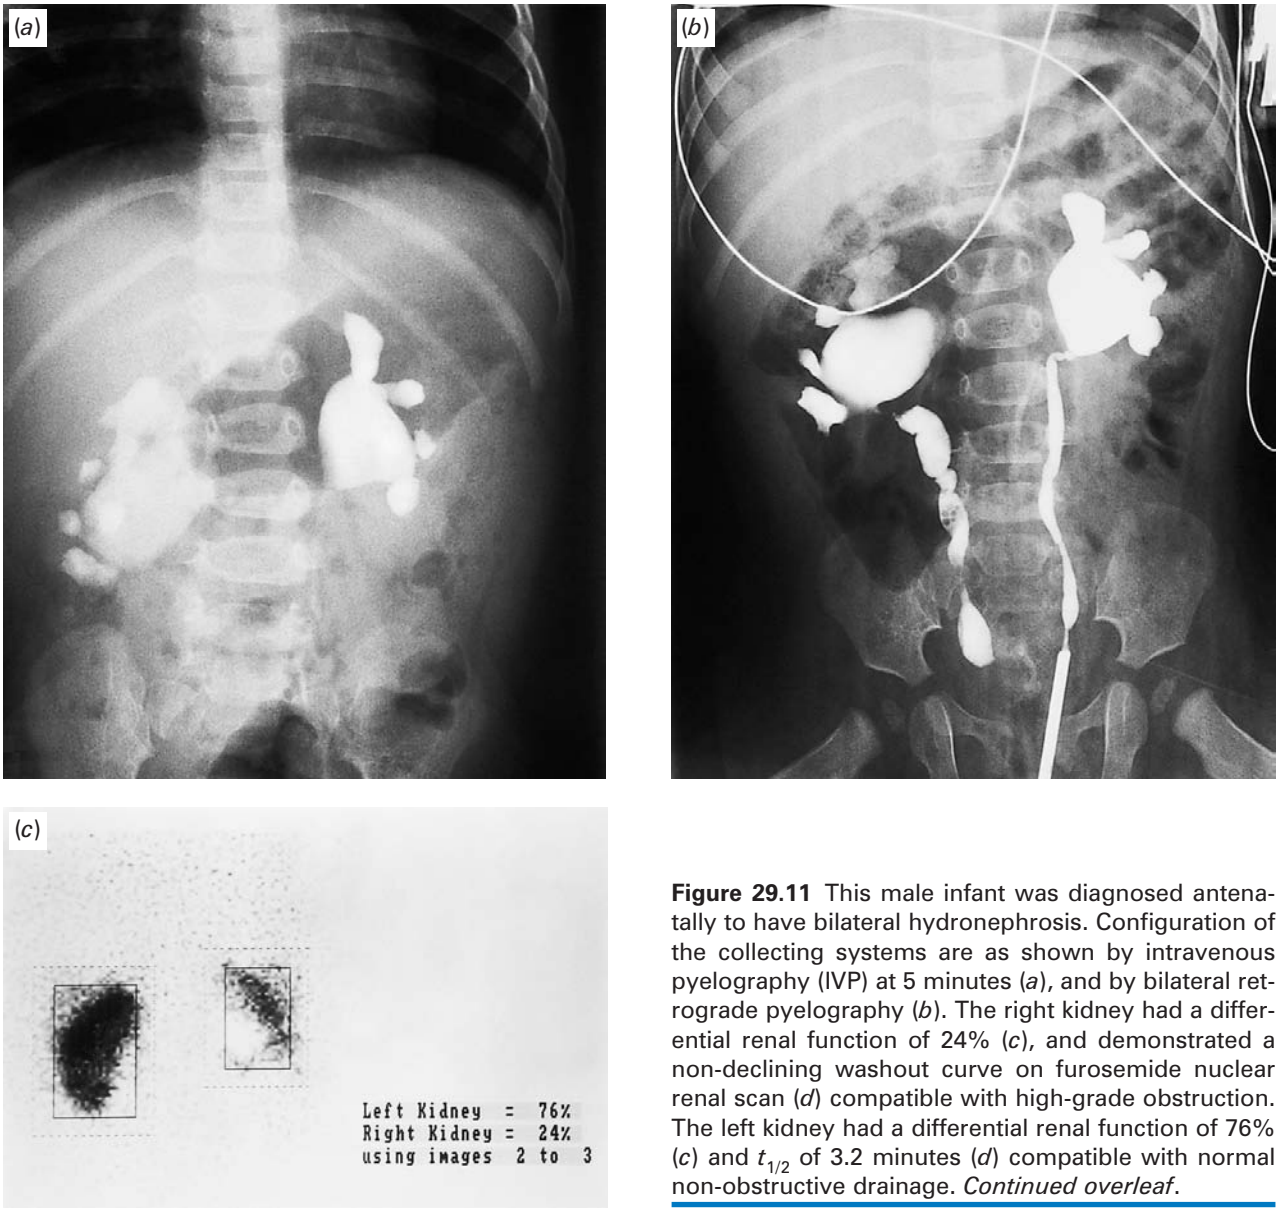
Diuretic Doppler sonography is a non-invasive test wherein the renal unit is stressed by a pharmacologically induced diuresis much like the diuretic pressure–flow study. Instead of monitoring renal pelvic pressure before and after the administration of furosemide, intrarenal resistive index (RI) is measured at regular intervals during a diuretic Doppler sonography study.[4] Resistive index is calculated based on an arterial Doppler waveform (Figure 29.10), and is defined as:

$$\text{resistive index} = \frac{\text{peak systolic velocity} - \text{end diastolic velocity}}{\text{peak systolic velocity}}$$

The resistive index is a measure of arterial resistance,[17] and is usually expressed as a percentage. Intrarenal RIs are generally recorded from the arcuate or interlobar arteries.[18]

Initial enthusiasm for using intrarenal RI to assess hydronephrosis stemmed from the observation that obstructed kidneys tend to be associated with elevated intrarenal RIs.[19] As obstructed kidneys are well documented to eventually develop a compensatory decrease in renal blood flow, it seemed promising that intrarenal RI might reflect this important physiologic compensation. Kidneys that developed acutely rising renal pelvic pressure were observed to also develop a progressive increase in intrarenal RIs.[4] This positive correlation suggested the possibility that instead of monitoring renal pelvic pressure during a relatively invasive diuresis pressure–flow study, intrarenal RIs could be monitored non-invasively instead (Figure 29.11).

However, using pressure–flow study results in 50 patients as the standard, there was no discernible



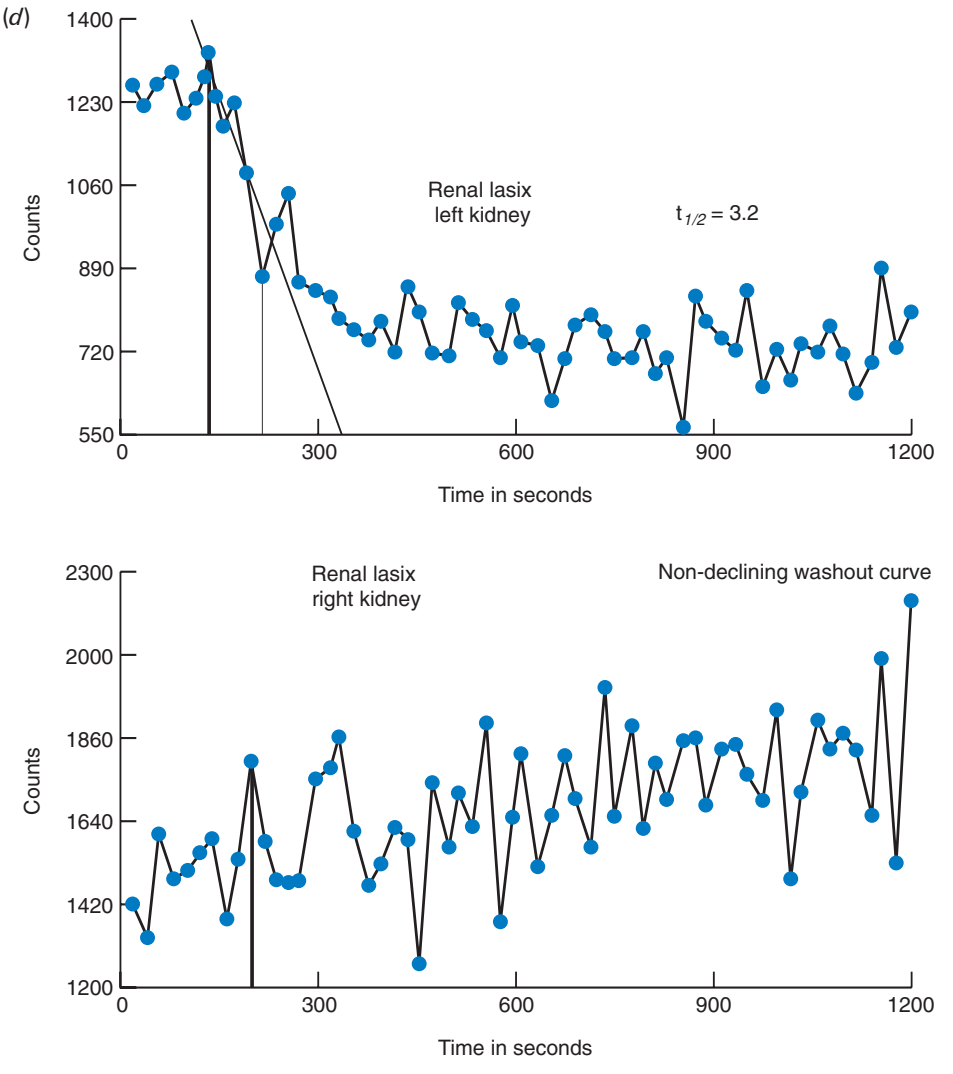


Figure 29.11 This male infant was diagnosed antenatally to have bilateral hydronephrosis. Configuration of the collecting systems are as shown by intravenous pyelography (IVP) at 5 minutes (*a*), and by bilateral retrograde pyelography (*b*). The right kidney had a differential renal function of 24% (*c*), and demonstrated a non-declining washout curve on furosemide nuclear renal scan (*d*) compatible with high-grade obstruction. The left kidney had a differential renal function of 76% (*c*) and $t_{1/2}$ of 3.2 minutes (*d*) compatible with normal non-obstructive drainage. *Continued overleaf*.

pattern that emerged from the diuretic Doppler sonogram. The reproducibility of any given RI reading was found to be poor, with widely variable measurements from one reading to the next.[20]

At present, there is no known diagnostic modality that can non-invasively and reliably demonstrate the changes in the upper tract urodynamics of obstructed as compared with normal collecting systems.

Summary

Prenatally detected hydronephrosis is a dynamic process, in which the initial presentation does not necessarily correlate with the ultimate outcome. There is currently no standard test that is uniformly successful at predicting the prognosis of hydronephrotic kidneys, or delineating whether surgical intervention is necessary for the prevention of deterioration in renal function. Of the available methods of assessment, upper tract urodynamics offers the most accurate, albeit more invasive, way of defining the mechanics of fluid handling by a hydronephrotic system. Of the parameters described, the resting or initial renal pelvic pressure, the maximum pressure obtained after induced diuresis, and the ureteral opening pressure appear to be of value in determining the resistance intrinsic to the collecting system, which in

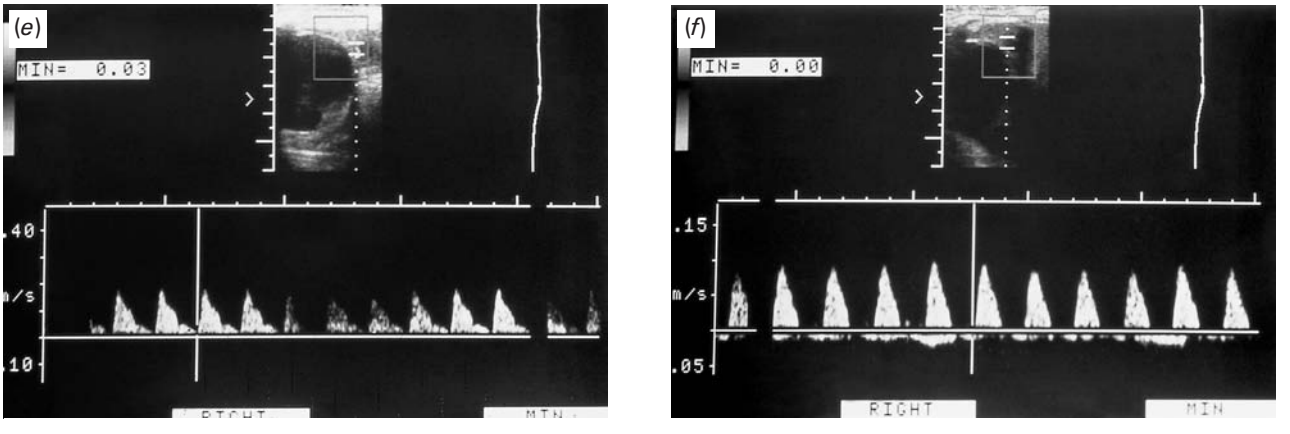

Figure 29.11 *Continued* Resistive index (RI) of the right kidney was 0.82 (82%) (*e*) at baseline, but rose to 1.00 (100%) with a complete cessation of diastolic flow after the administration of furosemide (*f*).

This dramatic increase in RI is presumably due to the furosemide-induced diuresis causing an increase in renal arterial blood flow as reflected by the elevation in RI. Although this case illustrates how changes in RI can non-invasively reflect important alterations in a hydronephrotic kidney with significant obstruction, we subsequently found that there are tremendous variabilities in RI measurements. This poor reproducibility of RI measurements renders the index unsuitable for reliably distinguishing non-obstructed from significantly obstructed hydronephrotic kidneys.

turn provides important information for the diagnosis of obstruction.

Not every individual who presents with hydronephrosis requires upper tract urodynamic studies. Obstruction can often be ruled out by less-invasive investigations, or the need to proceed to surgical relief of obstruction may be obvious. Upper tract urodynamic studies in the form of antegrade pressure–flow studies are particularly useful in those select patients in whom a clear diagnosis of obstruction is not forthcoming, despite persisting or worsening dilatation of the collecting system on anatomic studies, where the alternative is serial observation for signs of deterioration in renal function. Once deterioration in renal function is detected, subsequent treatment in correcting the obstruction in the collecting system may no longer be able to reverse the deterioration in renal function, but may merely stabilize it from further deterioration. The use of upper tract urodynamic studies in appropriately selected cases may therefore help the clinician detect and treat significantly obstructed kidneys, before deterioration in renal function occurs.

Ureteropelvic junction obstruction and multicystic dysplastic kidney: surgical management

30

Michael C Carr

The surgical management of a kidney with obstruction at the ureteropelvic junction (UPJ) has many nuances with respect to approach, degree of invasiveness, and timing of surgery. The objectives remain the same: to relieve the obstruction and thus preserve or improve the overall renal function and to maintain normal development while lessening the morbidity to the patient and yet not compromise the surgical outcome. Pyeloplasties remain among the most rewarding surgeries that we, as surgeons, perform.

Once a surgeon diagnoses a UPJ obstruction, prompt intervention is necessary to relieve the obstruction, provide for appropriate drainage, and reduce the intrapelvic pressure and stasis that contribute to progressive renal damage. This is particularly important in the neonatal period in order to maximize functional renal development and increase the ultimate number of perfused and filtering nephrons.[1] In those kidneys where the differential function is less than 10%, a temporary nephrostomy tube or double-J stent placement may allow for differentiating kidneys with recoverable function from those with irreversible damage.[2,3] Renal biopsies may also be performed to identify diffuse glomerulosclerosis that would indicate little chance for improved postpyeloplasty function.[4] No test, though, is reliable to predict renal recoverability.

Technical points of pyeloplasty or simple nephrectomy

A standard flank, anterior subcostal, or posterior lobotomy skin incision may be used to expose the kidney for pyeloplasty or nephrectomy. I recommend the flank approach with mobilization of the kidney for older patients. In older patients, the position of the kidney is more difficult to predict. If the incision is made too low or too high, the exposure may be difficult. In the child, however, where the back muscles are less well developed, most pediatric urologists favor an anterior extraperitoneal approach or a dorsal lumbotomy incision. The anterior extraperitoneal approach is perfomed as follows. A subcostal incision is made after the patient is placed supine, with a roll placed transversely beneath the patient to elevate the flank (Figure 30.1). An incision is made from the edge of the rectus muscle to just below the tip of the 12th rib. An intraoperative retrograde pyelogram allows one to identify precisely the position of the UPJ and aids in the placement of the incision. Each muscle layer encountered is split in the direction of the muscle fibers until the surgeon defines Gerota's fascia by sweeping the peritoneum medially. The fascia is then incised posterior to the lateral aspect of the kidney. The renal pelvis is identified by medial

Figure 30.1 Appropriate positioning of a patient for a left anterior subcostal incision. The tip of the 11th and 12th ribs have been outlined and a 4 cm incision has been drawn.

retraction of the peritoneum and lateral traction of the kidney. If the pelvis is dilated, an angiocath can be inserted to decompress the pelvis and facilitate identification of the UPJ.

I tend to use the lumbotomy approach in infants and younger children. A transverse skin incision, which follows Langer's lines to avoid postoperative spreading of the scar, is made with subsequent mobilization of the skin before a vertical incision through the lumbodorsal fascia allows the surgeon direct access to the renal pelvis. I try not to move the kidney too much (Figure 30.2).

The closure is in one layer, which shortens operative time. In the case of bilateral UPJ obstruction, the surgeon may approach both sides without repositioning the patient. The lumbotomy approach is contraindicated if one is dealing with an incompletely rotated anterior renal pelvis. If there is an anomaly of position, the surgeon must locate the position of the UPJ before planning the incision. If the obstructed pelvis is mostly intrarenal, small or high, then a lumbotomy approach may be more difficult. In addition, muscular patients with a steep angle between the spine and the 12th rib may also present difficulties with exposure of a small or high pelvis. If caught unprepared with a particularly superior renal pelvis, the 12th rib can be disarticulated and rotated cranially to improve exposure, but in these cases I usually favor an anterior approach.

Figure 30.2 Appropriate positioning of a patient for the left posterior lumbotomy approach. A curvilinear incision is marked, which can be used, or a transverse skin incision can be employed.

The flank approach is another option. The child is placed over the kidney rest in a flank position; the kidney rest is elevated and the operating room table is flexed. The incision is made anterior to the tip of the 12th rib, or if necessary, a supracostal 12th rib incision is made. Both the external oblique and latissimus dorsi muscles are divided. Next, the internal oblique and serratus posterior inferior muscles are divided. A transversalis muscle is often thin and can be separated with digital dissection. The peritoneum is identified and retracted medially. Gerota's fascia is then encountered and opened longitudinally to gain exposure to the perinephric space. Following identification of the renal pelvis and the ureter, the pyeloplasty is performed.

In a redo pyeloplasty, the anterior transperitoneal approach is preferred. Once the colon is reflected, the anatomy can be rapidly identified and damage to the ureter, renal pelvis, or renal vessels can be avoided by exploring a scarred retroperitoneum through a posterior approach to the kidney.

In the situation of a simple nephrectomy to remove a multicystic dysplastic kidney, any of the above-described approaches is applicable. If a small incision is utilized, decompression of the largest cysts will optimize exposure and allow for improved visualization of the renal hilum. Invariably the renal vasculature is atretic in most situations, but careful dissection will avoid meddlesome bleeding. Bipolar cautery can be advantageous for such a dissection.

Surgical repair

The successful pyeloplasty depends on a carefully designed anastomosis with care taken to ensure that the ureter and pelvis will lie in a normal anatomic position at the completion of the pyeloplasty. In the past, surgeons have described various techniques to repair the UPJ, with open approaches being divided into three main groups: the flap type, the incisional-intubated type, and the dismembered type. The

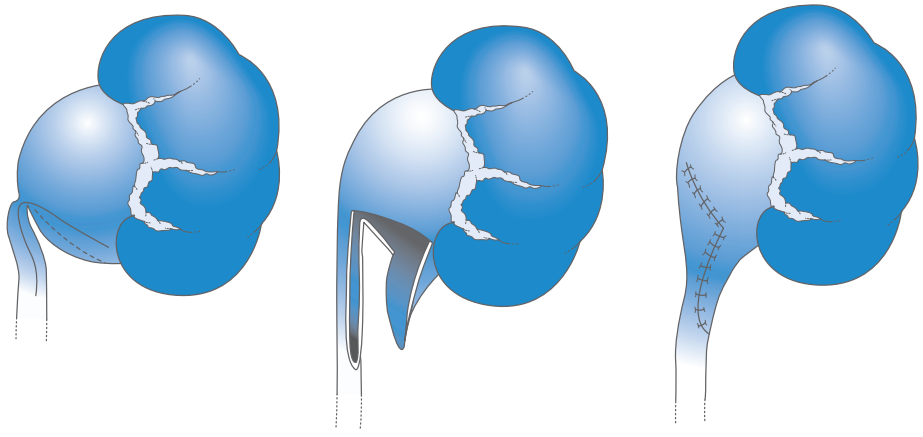

Figure 30.3 Foley Y–V plasty.

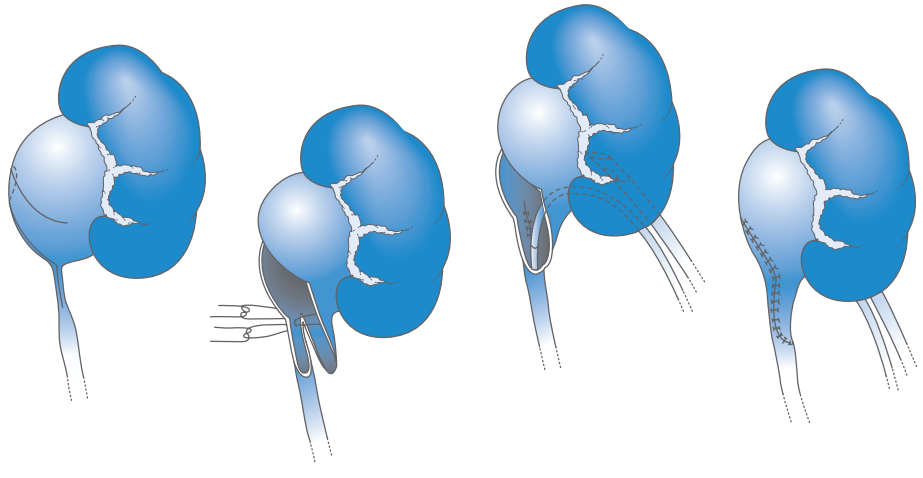

Figure 30.4 Culp–DeWeerd spiral flap ureteropelvioplasty.

incisional techniques included incision through the strictured area with healing over a stent. This approach is no longer used with open repair. The older flap techniques maintained the continuity of the ureter and pelvis and included the Foley Y–V plasty and the Culp spiral flap. The Foley operation was designed for the correction of UPJ with a high ureteral insertion (Figure 30.3).[5] This technique cannot be used in conjunction with transposition of a lower pole vessel, nor does it allow for any reduction of the renal pelvis. If this redundant pelvis remains at the completion of the pyeloplasty, then a fixed kink with resultant obstruction may persist. Culp and DeWeerd's spiral flap is created from the renal pelvis, which is then used to repair the defect at the UPJ. Such a flap is able to bridge the gap between the pelvis and healthy ureter over a distance of several centimeters (Figure 30.4).[6] Scardino and Prince[7] used a vertical flap that was designed in a situation of a dependent UPJ with a large, square-shaped extrarenal pelvis (Figure 30.5).

The approach of dismembering the ureter was born out of necessity in the repair of a retrocaval ureter (Figure 30.6).[9] This technique was slow to gain popularity because of the reluctance of surgeons to sever the apparent neural continuity between pelvis and ureter. Experimental work demonstrated that the arborization of blood vessels in the renal pelvis would ensure appropriate healing even with dismembering. Despite the theoretical risk of poor coordination of peristalsis across the incised and reconstructed UPJ, the reconstructed pelvis empties well following successful dismembered pyeloplasty.

The renal pelvis and upper ureter must be carefully handled to maintain the integrity of the blood supply. The tissues surrounding the ureter should not be trimmed or separated from the ureter. Placement of several traction sutures in the renal pelvis and the

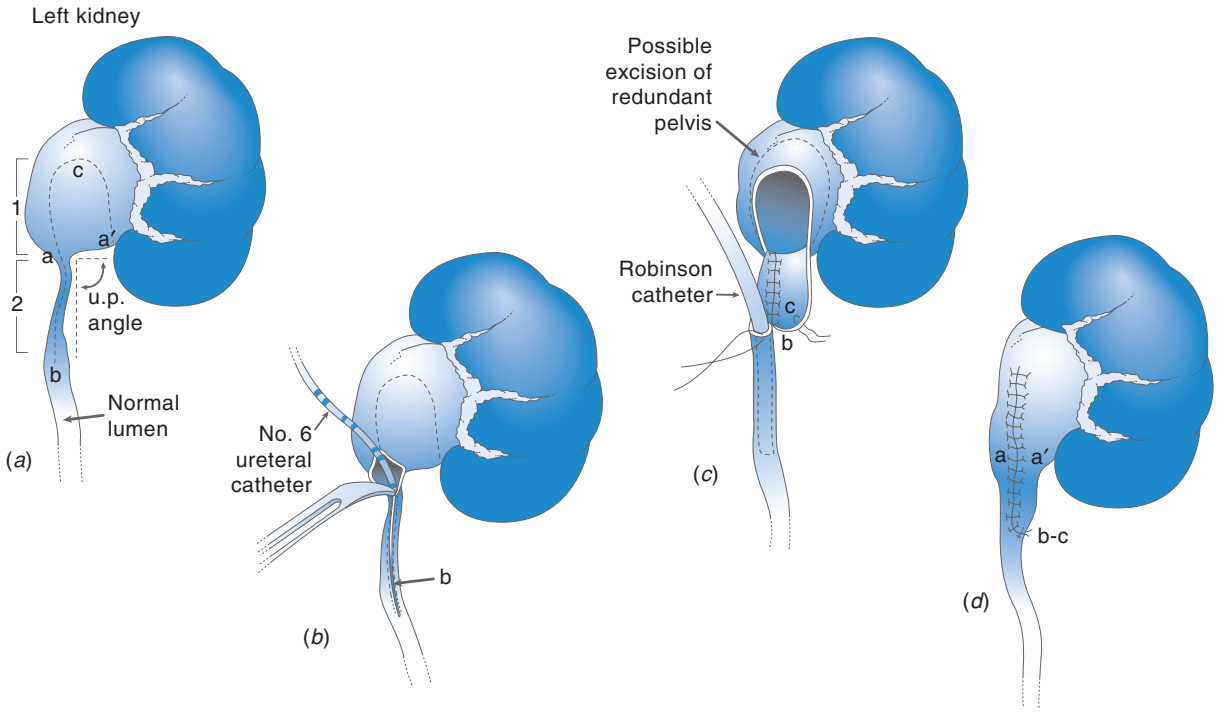

Figure 30.5 Scardino–Prince vertical flap pyeloureteroplasty. (*a*) The length of the pelvic flap (1) should adequately traverse the segment of ureteral obstruction (2). (*b*) A pyelotomy incision is made in the lower pelvis along the medial border of the proposed pelvic flap incision. A 6 Fr catheter is used to cannulate the ureter and the tip of a #12 blade is inserted into the catheter. The catheter acts as a guide to make a clean, precise ureterotomy incision. (*c*) A 5–0 Prolene (Ethicon, Inc.) suture is placed within the ureteral wall at the lower angle of the ureterotomy. A rounded pelvic flap is fashioned and a second traction suture is placed in the tip of the flap. A 7–0 Maxon (Davis–Geck, Inc.) or comparable suture is used to sew the medial margin of the flap to the lateral ureteral margin. The mucosa margins should be identified for accurate approximation. (Adapted from Schaeffer and Grayhack.[8]) (*d*) The tip of the flap (c) is carefully sutured into the lower angle of the uterostomy (b). Any redundant pelvis may be excised and the anterior margins reapproximated (b and c, a and a).

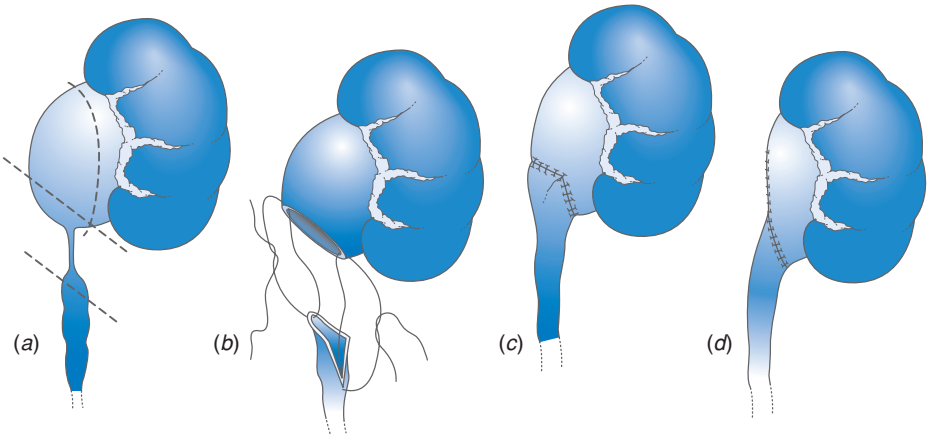

Figure 30.6 Anderson–Hynes dismembered pyeloplasty. (*a*) Two options: pelvis may be reduced in size or not. (*b*) and (*c*) Anastomosis alone is performed. (*d*) A reduction pyeloplasty is included.

anterior aspect of the ureter facilitates this dissection and minimizes the handling of the tissues. We then open the ureter opposite the traction suture distally into the healthy tissue just below the poorly peristaltic segment. A fine pair of forceps will open the ureteral lumen as the ureter is divided using a straight pair of Pott's scissors. The forceps should spring apart once the scissors meet the healthy ureter distal to the

obstructing segment. Bleeding from the cut edge of the urothelium, which is usually diminished in the region of the obstructed segment, will be brisk when the normal urothelium is opened distal to the obstruction. As long as the renal pelvis is not reconstructed before examination of the ureter, if the aperistaltic segment is unusually long, a flap can be fashioned from the pelvis to help bridge a discontinuity between renal pelvis and distal ureter that may be created with removal of a long ureteral segment. A ventral rotational flap from the lower portion of the pelvis can be used to bridge a gap of 2–3 cm: more if the kidney is mobilized. Reduction of the renal pelvis is completed before beginning the anastomosis. Prior to the anastomosis, the interior of the renal pelvis should be inspected to precisely identify the anatomy of the renal pelvis and its relationship to the lower pole infundibula. In some cases, a very dilated pelvis may be associated with dilated, extrarenal infundibula. In these cases, it is possible to unknowingly create the ureteral pelvic anastomosis in such a manner that the lower pole infundibulum, rather than the renal pelvis, is anastomosed to the ureter. If this occurs, the upper portions of the collecting system will be bypassed and will fail to drain. If an infundibulum is divided, a Heineke–Mikulicz advancement can satisfactorily prevent this complication. In the face of aberrant lower pole vessels that contribute to the UPJ obstruction, the appropriate repair is to divide the ureter below the UPJ and perform a standard dismembered pyeloplasty with reconstruction of the UPJ anterior to the offending vessel or vessels.

Tissue handling, sutures, and stenting

The judicious use of traction sutures allows for minimal handling of the pelvis and ureter. The more the surgeon handles (or mishandles) the tissue, the more postoperative edema will result. Without the use of urinary diversion, attention to atraumatic handling of the tissues becomes critical. In mobilizing the pelvis, similar care is required. An avascular plane is usually located outside the intrinsic blood supply of the pelvis, unless there has been significant preoperative infection or extravasation of urine around the kidney that makes mobilization of the pelvis more difficult.

Monofilament absorbable suture is preferable for performing a dismembered pyeloplasty. I prefer 7–0 Maxon suture (Davis–Geck, Inc.) for the majority of children, regardless of age. Construction of the anastomosis begins at the apex, with meticulous placement of sutures allowing for eversion of the mucosal edges and a watertight anastomosis. Some surgeons prefer interrupted sutures to prevent reduction of the anastomotic diameter; others employ a running closure. Before completing the anastomosis, it is helpful to place a small angiocath or feeding tube in the renal pelvis to irrigate the reconstructed pelvis free from clotted blood.

Antegrade placement of a double-J stent is fraught with hazard, particularly in infants. It is safe for the surgeon to place a small feeding tube several centimeters below the anastomosis. If the tube is advanced to or through the intramural portion of the ureter however, the catheter may traumatize the ureterovesical junction and raise a mucosal flap that can lead to a permanent obstruction requiring redo surgery.[10] Either preoperative retrograde pyelography or antegrade visualization of the ureter with placement of the catheter over a wire under fluoroscopic guidance may help prevent this complication.[11]

Surgeons continue to debate the use of internal stenting versus the use of nephrostomy tubes. A routine dismembered pyeloplasty with minimal handling of the tissues may not warrant the placement of either nephrostomy tube or internal stent. Advances in instrumentation, sutures, and technique have enabled the construction of such a satisfactory anastomosis that even if transient leakage from the anastomosis occurs after surgery, a very satisfactory outcome is likely. A Penrose drain left in the proximity of the anastomosis to ensure that a perinephric urinoma does not occur is required in these cases. A child with persistent drainage from the Penrose drain can be discharged from the hospital with the drain still in place. For the most part, however, drainage gradually ceases after the first few days following surgery, and then the Penrose drain can be safely removed.

The routine use of a nephrostomy tube is a very safe approach, with few complications.[12] Selective use of a nephrostomy tube, particularly in the child with a solitary or poorly functioning kidney or a very small infant where the ureter may be not nearly as robust as in a toddler, is usually preferable. The nephrostomy tube not only prevents high renal pelvic pressures if there is transient edema at the anastomosis but also provides access for radiographic studies before removal of the tube.

In a redo pyeloplasty, scarred urothelial tissue may result in greater difficulty when performing a watertight anastomosis. For this reason, I recommend a nephrostomy tube along with a small silastic stent across the anastomosis for 3–5 days following

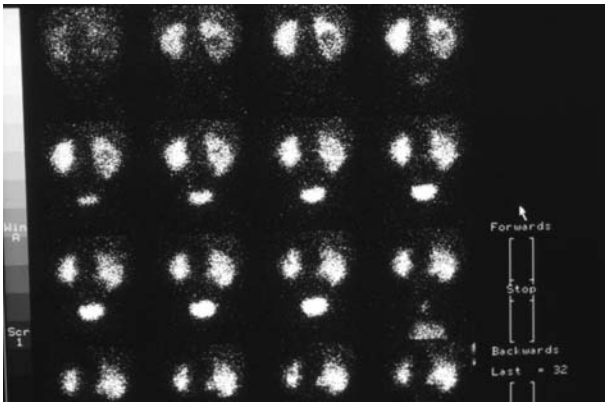

Figure 30.7 A MAG3 lasix renogram demonstrating normal right upper pole perfusion and excretion with delayed uptake and excretion to lower pole, consistent with lower pole UPJ obstruction.

surgery. I remove the stent before the nephrostomy tube so that a subsequent nephrostogram can be performed to ensure that the anastomosis is patent before removal of the tube.

Ureteropelvic obstruction in a duplex kidney

A UPJ obstruction can occur in a duplex kidney. Although the obstruction can occur in either the upper or the lower pole, because the lower pole is nearly always dominant and associated with the renal pelvis, in practice the UPJ obstruction is nearly always encountered in the lower pole system. When this occurs, hydronephrosis is noted in the lower pole of a kidney on ultrasound, or a diuretic renogram shows a small, non-obstructed upper pole segment (Figure 30.7).

The anatomy of the duplication of the ureter dictates the type of procedure required. If the ureter is incompletely bifid and there is a long lower pole ureteral segment, then a standard dismembered pyeloplasty is appropriate. However, more commonly, a high bifurcation of the ureter is present and the segment of the lower pole ureter distal to the obstruction may not be long enough to permit direct ureteropyelostomy. In this situation, the renal pelvis is anastomosed to the side of the upper pole ureter (Figure 30.8). The lower pole ureter may be opened with an incision that runs through the bifurcation with the upper pole ureter. The anastomosis is the same as for a single-system kidney except that an apex is present at either end of the lower pole pelvis. Meticulous care with the suture placement at the apices is important because the anastomosis will be narrow at these two points. If the anastomotic sutures are placed in discordant positions, the lumen at either apex will be narrowed, resulting in surgical failure.

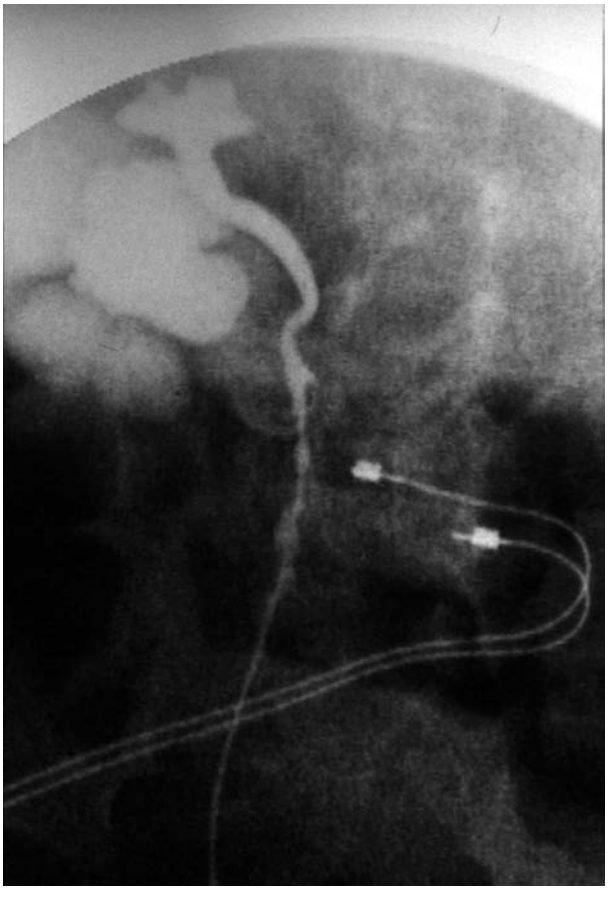

Figure 30.8 Anatomy of right lower pole UPJ obstruction with atretic lower pole ureter. An end-to-side anastomosis between the lower pole renal pelvis and upper pole ureter is favored.

Ureterocalicostomy

In redo surgery, or in cases where the pelvis is intrarenal, or the relative length of the obstructed ureteral segment to the renal pelvis is unusually long, or if there is an unusually small intrarenal pelvis, the proximal ureter distal to the obstruction may be anastomosed to a dependent lower pole calyx instead of to the renal pelvis. Success depends upon amputation of an adequate portion of the renal parenchyma in order to facilitate the anastomosis between the calyx and the ureter. This procedure is therefore best suited for kidneys with a large, dilated lower pole calyx with over-

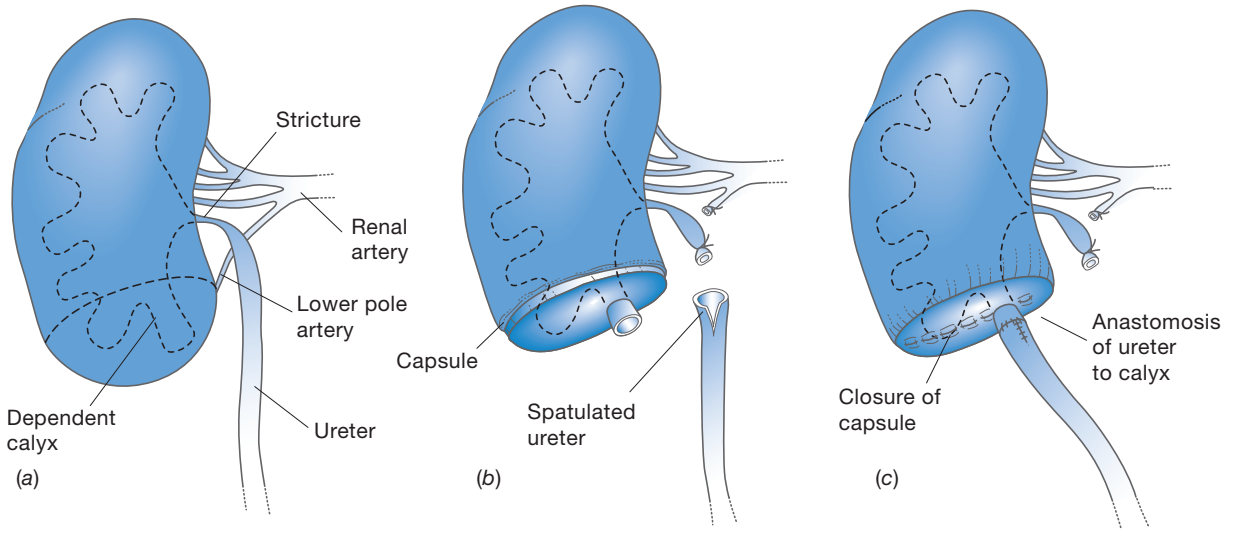

Figure 30.9 Ureterocalicostomy of a kidney with an intra-renal pelvis and preserved lower pole parenchyma (*a*) lower pole arterial supply is ligated; (*b*) the lower pole is resected exposing dependent calyx; (*c*) anastomosis of ureter to calyx is accomplished without tension.

lying parenchymal thinning. The calyx must be partially mobilized to create a tension-free, urothelium-to-urothelium anastomosis (Figure 30.9). There should be no remaining renal cortex at or below the level of the repair. Redundant renal capsule, omentum, or perinephric fat can then be used to cover the repair to minimize postoperative scarring. I recommend stenting of the anastomosis with a double pigtail stent or nephroureteral stent in addition to a Penrose drain.[13]

Outcome

Adherence to sound surgical principles, minimal handling of the ureter at the time of the repair, and judicious use of internal stenting or nephrostomy tube drainage may all help to ensure a successful outcome. I have found that the use of bipolar cautery is useful, particularly around the renal hilum where the blood supply may be suspect.

Postoperative imaging of the kidney depends on whether a nephrostomy tube or an internal double-J stent has been used. A nephrostogram performed 10–14 days after surgery allows for visualization of the anastomosis. If a double pigtail ureteral stent is left indwelling, it is removed 2–6 weeks after the initial procedure. A renal ultrasound is obtained 6–8 weeks after pyeloplasty or following stent removal to ensure that the hydronephrosis (pelvicaliectasis) is improving. An overall decrease in the degree of pelvicaliectasis over time is a good indication that the obstruction has been relieved. Long-term imaging at 3 years may be carried out to look for the rare situation of delayed scarring and narrowing of the UPJ. Modern open repairs can be performed with an overall success rate exceeding 97%.[14]

Laparoscopic nephrectomy and pyeloplasty

31

Alaa El-Ghoneimi

For decades pediatric urologists have been performing laparoscopy for non-palpable testis. The passage from diagnostic to therapeutic indications has been a long and hesitating procedure for pediatric urologists. During the 1990s laparoscopic renal surgery was limited to ablative indications and was used only in a limited number of centers. In the early experience of the procedure, the indications for laparoscopy in pediatric urology were unclear and unproven compared with the advantages of open procedures. It is only in the last several years that laparoscopy has been considered an essential part of the armamentarium of pediatric urologists.

This chapter will address first the established technique of laparoscopic nephrectomy and secondly the developing and more challenging laparoscopic pyeloplasty.

Laparoscopic nephrectomy

The first laparoscopic nephrectomy in adults was reported in 1991 by Clayman et al,[1] and 1 year later Ehrlich et al[2] reported their first series of pediatric cases. Since then, many authors have reported successful results of nephrectomy and nephroureterectomy in pediatrics, all advocating the transperitoneal approach.[3,4] Roberts[5] suggested the retroperitoneal approach to the kidney in 1976, reporting his experience with retroperitoneal endoscopy with gas insufflation in animals. Retroperitoneal operative laparoscopy was described for the first time by Gaur[6] in 1992 and then by others in adult and pediatric urology.[7–9] The application of retroperitoneal laparoscopic renal surgery in adults has increased,[10,11] and the technique has been adapted by pediatric surgeons and its use for pediatric patients is also expanding.[9,12–15]

Most nephrectomies in children are performed for non-functioning kidneys secondary to obstructive uropathy, reflux, or ectopic implantation of the ureter. The laparoscopic approach is excellent for most of these cases.[12,16]

Currently, malignant renal tumors in children are not considered for laparoscopy. The most common renal tumor in children is nephroblastoma. These tumors are of large size, frequently extending outside the kidney, and with high risk of rupture during dissection. Indications for nephrectomy in children are mainly for non-functioning kidneys secondary to obstructive uropathy or reflux. Although, laparoscopic nephrectomy for multicystic dysplastic kidney (MCDK) is an easy and safe procedure, the indications for nephrectomy are still debatable: the acceptable indications are increasing size of cysts or complications of hypertension or infection, both of which are unusual.[17]

Nephrectomy may be indicated in children with end-stage renal disease before transplantation when the primary renal disease is associated with hypertension, severe nephrotic syndrome, or severe hemolytic uremic syndrome. During open surgery in these children, a large incision is necessary to control the renal pedicle and to extract a large kidney, and therefore the laparoscopic approach is particularly advantageous for this population.[18] In a few cases of severe congenital nephrotic syndrome, simultaneous bilateral nephrectomy is indicated early in life. In our experience with 13 simultaneous bilateral nephrectomies using a lateral retroperitoneal approach, 7 patients were under 1 year of age.[19] To avoid positioning the patient twice for bilateral nephrectomy, the procedure can also be performed through a posterior retroperitoneal approach, with the child positioned prone.[20] In this specific group of pretransplant nephrectomy patients, a bag is recommended to retrieve the kidney, to

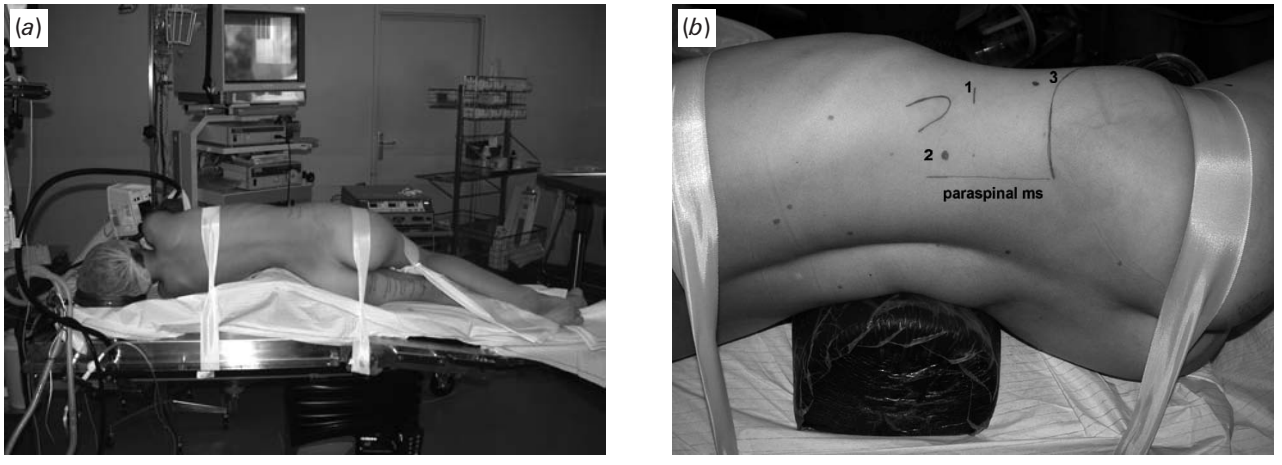

Figure 31.1 Patient positioning for right retroperitoneal laparoscopic renal surgery. The patient is placed lateral, with sufficient flexion of the operating table so as to expose the area of trocar placement (*a*), between the last rib and the iliac crest; for younger children, as shown, a lumbar support is sufficient for the exposure (*b*). The child is wrapped by two adhesive bands, one at the greater trochanter level and the other on the chest to keep the child at a perpendicular angle to the table. The surgeon, assistant, and scrub nurse are all behind the child. The front of the child is left free for the monitor, which is placed cranial while doing the kidney dissection and caudal to proceed for the distal ureterectomy. Retroperitoneal access is achieved through the first incision (1), 15–20 mm in length, and one finger width from the lower border of the tip of the 12th rib. A second trocar (2) is inserted posteriorly in the costovertebral angle. The third trocar (3) is inserted, in the anterior axillary line, a finger width from the top of the iliac crest.

reduce postoperative retroperitoneal adhesions. These adhesions were noted during renal transplantation in children who underwent kidney fragmentation during extraction without a bag.[19] Recently, Zuniga et al reported the first case of transperitoneal bilateral nephrectomy in a young child aged 6 months. This option has the advantages of limiting the number of trocars and of also being able to deal with large kidneys in small children.[21]

Nephrectomy for xanthogranulomatous pyelonephritis is a challenging procedure because of the perirenal adhesions to the great vessels and to the surrounding viscera. Halachmi et al suggested the subcapsular dissection of the upper part of the kidney to avoid lesions to the duodenum and the adrenals on the right side.[22]

Renal access

The kidney can be accessed by a retroperitoneal or a transperitoneal approach.

Retroperitoneal access

Lateral approach

The patient is placed lateral, with sufficient flexion of the operating table so as to expose the area of trocar placement, between the last rib and the iliac crest (Figure 31.1). In infants and young children (under 6 years), our preference is to use lumber padding to laterally flex the patient without flexing the operating table. Retroperitoneal access is achieved through the first incision, 15–20 mm in length, and one finger width from the lower border of the tip of the 12th rib (see Figure 31.1b). The use of narrow retractors with long blades allows a deep dissection despite a short incision. Gerota's fascia is approached by a muscle-splitting blunt dissection; it is then opened under direct vision, and the first blunt trocar (5 or 10 mm) is introduced directly inside the opened Gerota's fascia (Figure 31.2). A working space is created by gas insufflation dissection, and the first trocar is fixed with a purse-string suture that is applied around the deep fascia to ensure an airtight seal and to allow traction on the main trocar if needed to increase the working space. We prefer this type of fixation to the disposable self-retaining trocar, which we find to be relatively large and interfering with the mobility of instruments. A second trocar (5 mm) is inserted posteriorly in the costovertebral angle, in front of the lumbosacral muscle. A third trocar (5 mm) is inserted, in the anterior axillary line, a finger width from the top of the iliac crest. To avoid transperitoneal insertion of this trocar, the working space is

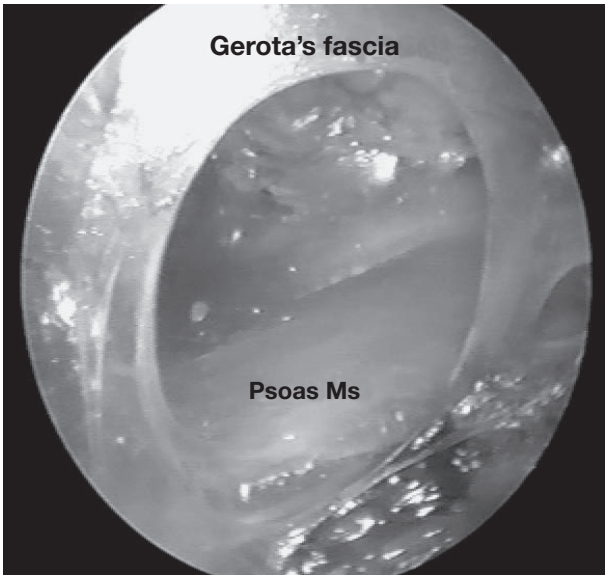

Figure 31.2 Gerota's fascia is approached by a muscle-splitting blunt dissection; it is then opened under direct vision, and the first blunt trocar is introduced directly inside the opened Gerota's fascia to start insufflation without the need for a balloon to create the working space. The psoas muscle is the landmark after opening the Gerota's fascia; it must remain on the bottom of the screen during surgery.

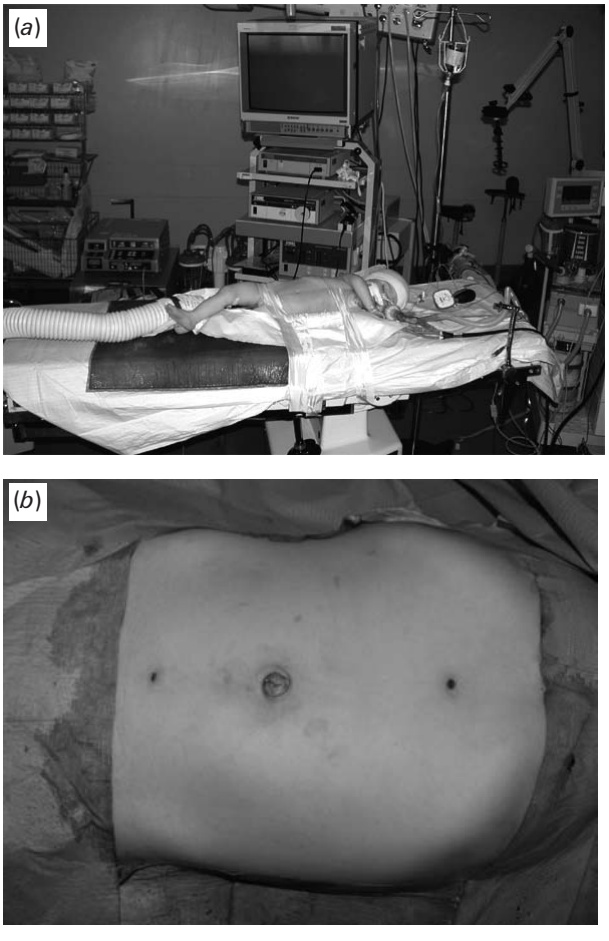

Figure 31.3 Patient positioning and trocar placement for transperitoneal laparoscopic renal surgery. The child is positioned with the surgeon standing in front of the abdomen (*a*) (opposite side of the kidney). The first port, for the laparoscope, is inserted under vision through the umbilicus. The two operating ports are inserted in the midline line above and below the umbilicus (*b*). A fourth trocar may be placed in the mid-clavicular line, if needed for exposure.

fully developed and the deep surface of the anterior wall muscles is identified before trocar insertion. Insufflation pressure does not exceed 12 mmHg, and the CO_2 flow rate is progressively increased from 1 to 3 L/min. Access to the retroperitoneum and creation of the working space are the keys to success in retroperitoneal renal surgery. Age is not a limiting factor for this approach. Young children have less fat and the access is easier; our youngest child was 3 weeks old.

Prone posterior approach

The access begins with an incision in the costovertebral angle at the edge of the paraspinous muscles. The secondary trocars are placed just above the iliac crest, one medially at the edge of the paraspinous muscles, and one laterally at the posterior clavicular line.[23] In a randomized prospective study on 36 complete and 19 partial nephrectomies, Borzi[24] compared the lateral to the posterior retroperitoneal approach in children. There was no significant difference in the operative time.

The author's preference is for the lateral approach; it permits any type of renal surgery at any age, with good exposure to the distal ureter.

Other techniques to access the retroperitoneal space

Since the description by Gaur,[6] balloon dissection has been the method applied by most urologists. Disadvantages of the balloon are the cost of the disposable material and the possible complications related to rupture of the balloon.[25] On the other hand, balloon dissection allows creating a working space without opening Gerota's fascia, which is important for radical removal of malignant tumors in adults.

Capolicchio et al[26] described a modification of lateral access. They recommend the insertion of the first trocar through the costovertebral angle. This modification helped them to avoid an accidental peritoneal

tear during access through the first lateral incision, and also allowed a smaller incision for the laparoscope.

Micali et al[27] reported the use of the Visiport visual trocar to access retroperitoneal space directly, which was originally described by Kavoussi. The advantage of this method is the possibility of using a small incision for the first trocar, which is helpful in reconstructive surgery but not in ablative surgery as the first incision is needed for organ retrieval.

Transperitoneal access

Several options exist in terms of patient positioning. The most frequently described is the flank position.[23] The pneumoperitoneum is created through an open umbilical approach. The child is positioned with the surgeon standing in front of the abdomen (opposite side of the kidney) (Figure 31.3a). The most frequent configuration has been with the umbilical port and two operating ports in the midline above and below the umbilicus (Figure 31.3b). A fourth trocar may be placed in the mid-clavicular line, if needed for exposure. The kidney is exposed by medial mobilization of the colon.

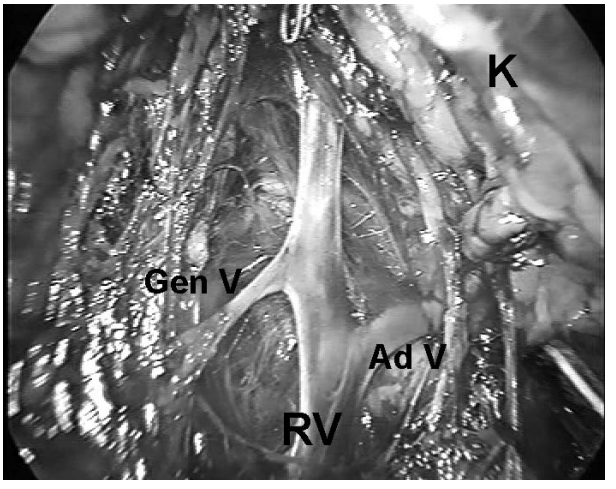

Figure 31.4 Retroperitoneal exposure and ligature of the renal pedicle. The landmarks of the retroperitoneal space are first identified in order to be oriented with the retroperitoneal exposure. The kidney (K) remains attached anteriorly to the peritoneum, and should remain upward on the screen. The renal pedicle is identified and approached posteriorly. In this picture, the artery is already ligated and sectioned. The left renal vein (RV) is dissected to identify the adrenal (Ad V) and the genital (Gen V) veins.

Nephrectomy by lateral retroperitoneal approach

The landmarks of the retroperitoneal space are first identified in order to be oriented with the retroperitoneal exposure. The psoas muscle is the posterior landmark, and should remain in the bottom of the screen. The kidney remains attached anteriorly to the peritoneum, and should remain upward on the screen. The renal pedicle is identified and approached posteriorly (Figure 31.4); it is dissected close to the junction with the aorta and vena cava, to avoid multiple ligations of branches of the renal vessels. On the left side, the vein is ligated distal to the genital and adrenal branches. On the right side, the vein is short and a careful dissection at its junction with the vena cava will avoid confusion with dissecting the vena cava. After dissecting the renal artery, and then the vein, the vessels are clipped, ligated, or coagulated. The choice of method depends on the vessel diameter and the surgeon's experience. In general, small arteries of MCDK can be coagulated using bipolar cautery or the harmonic scalpel, whereas the most common method is to double ligate the artery proximally by two clips and distally by one. The vein is generally clipped in the same way. If the diameter is longer than the length of the clip, the vein is first ligated by resorbable intracorporeal knot; the diameter is thus reduced, and the ligature is secured by juxtaposed clips. The use of staples, as described in adult nephrectomy, needs a 12 mm port and is not required for smaller pediatric patients. The ureter is then identified and dissected as far as necessary. In the absence of reflux, the ureter is coagulated and divided at the lumbar level (especially in pretransplant nephrectomy, the native ureter might be used for the transplantation). In the presence of reflux, the dissection is followed distally, the vas deferens is identified in males, and the ureter is ligated as close as possible to the ureterovesical junction. During this distal dissection, the surgeon moves towards the head of the child, and the screen goes towards the feet of the child. Early in our experience, we were using a fourth trocar to dissect and ligate the distal ureter.[12] Currently, we use an endoloop, or, if the ureter is large, a transparietal suture, to fix the ureter to the abdominal wall to facilitate its distal dissection and ligation. A fourth trocar is still used if the dissection is not sufficiently close to the bladder, and it is inserted at the edge of the lumbosacral muscle close to the iliac crest. As the peritoneum is very close to the ureter in this distal part, its dissection is left at the end of the procedure to avoid an early peritoneal tear.

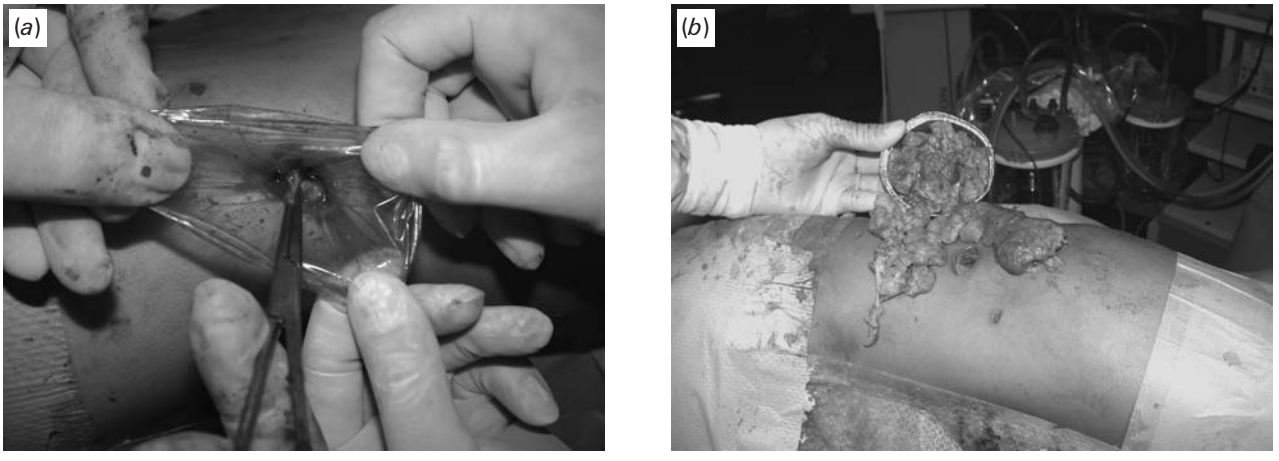

Figure 31.5 Kidney retrieval after retroperitoneal nephrectomy. The kidney can be extracted either directly through the main incision or inside an endoscopic specimen bag. (*a*) The endobag is introduced through the first trocar and the kidney is placed inside the bag. Morcellation of the kidney by an artery forceps under direct vision allows kidney retrieval without the need to extend the incision. (*b*) An 18 cm length polycystic kidney. The extraction bag was ruptured and the kidney retrieval was done by morcellating the kidney directly under the incision.

The last part of dissection is the anterior surface of the kidney. The kidney is dissected from the peritoneum very close to its capsule in the cleavage plane of areolar tissue. Usually no hemostasis is necessary in this plane, whereas, in inflammatory adherent kidneys, a sharp dissection with bipolar coagulation may be necessary. In the rare cases of xanthogranulomatous pyelonephritis, we carry out the dissection of the adherent kidney through the subcapsular plane to avoid injury to intraperitoneal structures.[28]

Kidney retrieval

The kidney is usually retrieved through the main incision (Figure 31.5). A 5 mm telescope is inserted through the accessory port, and a toothed grasping forceps is introduced through the first port to extract the kidney. The kidney is grasped at one of the poles, and pulled in this axis, to pull on the smallest diameter of the kidney. In most cases, the kidney can be divided under vision during extraction through the muscle wall. In cases of severe pyelocaliceal dilatation or MCDK, direct evacuation by puncture helps in organ retrieval. An endoscopic specimen bag is used for infected or large kidneys, and the kidney is morcellated inside the bag. Our current preference is for using the bag routinely for extraction to avoid extending the incision and spilling the parenchyma in the retroperitoneum, which might produce more postoperative inflammation. This is particularly important in the pretransplant group where we have to minimize all the factors that might increase postoperative retroperitoneal adhesions. In our experience these adhesions can render the vascular dissection during transplantation more difficult. If nephrectomy is concurrent with other lower urinary tract procedures, it is done first and the kidney is placed near the bladder without transecting the ureter. Retrieval is done through the Pfannenstiel incision.

Laparoscopic pyeloplasty

Open pyeloplasty remained the standard treatment for both adult and pediatric patients until the mid 1980s, when the morbidity associated with the flank incision led urologists to explore less-invasive alternatives. In the 1990s, the endourologic management of ureteropelvic junction (UPJ) obstruction became the treatment of choice in the adult population. Although the postoperative morbidity is significantly less after endoscopic procedures, the success rate does not exceed 80%.[29]

Laparoscopic pyeloplasty was introduced in adults in 1993.[30,31] In the initial report of 5 cases, the operative time ranged from 3 to 7 hours. The procedure has gained in popularity, and more recent series have reported a success rate of over 95%.[32] Laparoscopic pyeloplasty in children has followed the same evolution as nephrectomy. The procedure was first described through a transperitoneal approach. Tan[33] reported the first pediatric series of transperitoneal laparoscopic dismembered pyeloplasty in 18 children aged 3 months to 15 years old. Mean operative time

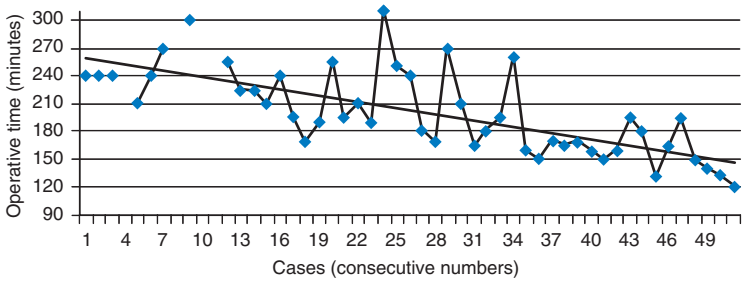

Figure 31.6 Retroperitoneal laparoscopic pyeloplasty learning curve. The figure represents the global experience of the author in retroperitoneal laparoscopic pyeloplasty. Each point corresponds to one child; 52 cases are consecutive from 1999 to 2004. Cases needing conversion to open surgery (4 cases, 8%) are not included as points on the operative time curve. Note the trendline (uninterrupted line) showing the progressive decrease of the mean operative time.

was 89 minutes. Two patients with persistent obstruction underwent repeat laparoscopic pyeloplasty.

Yeung et al[34] have reported their initial experience with retroperitoneal dismembered pyeloplasty in 13 patients, one of whom required open conversion. The mean operative duration was 143 (range 103–235) minutes. The longer time needed for the retroperitoneal approach is probably related to the limit of the working space, which renders suturing more difficult.

In our experience with 50 retroperitoneal laparoscopic pyeloplasties in children, aged between 22 months and 15 years, we had to convert to open surgery in 4 cases because of technical difficulties during suturing.[35,36] Mean hospital stay was 2 days, and return to full activities was within 5 days after surgery. After a mean follow-up of 18 months (range 6 months to 3 years), we had to redo 1 case for early persistent postoperative obstruction. The learning curve is significant; the mean operative time was reduced from 4 hours to 3 hours and there was no need for conversion in our last 35 cases.[36] The shortest operative time in our experience is 120 minutes, and our last 4 cases were under 150 minutes (Figure 31.6). An aberrant crossing vessel was found in 24 cases and dismembered pyeloplasty enabled ureteral transposition in all of them without conversion (Figure 31.7). In our current practice, children <2 years old are operated through a posterior lumbotomy to avoid the technical difficulties of suturing in young children through the retroperitoneal approach. We used a transperitoneal approach only in 5 cases of pyeloplasty in horseshoe kidney (unpublished data).

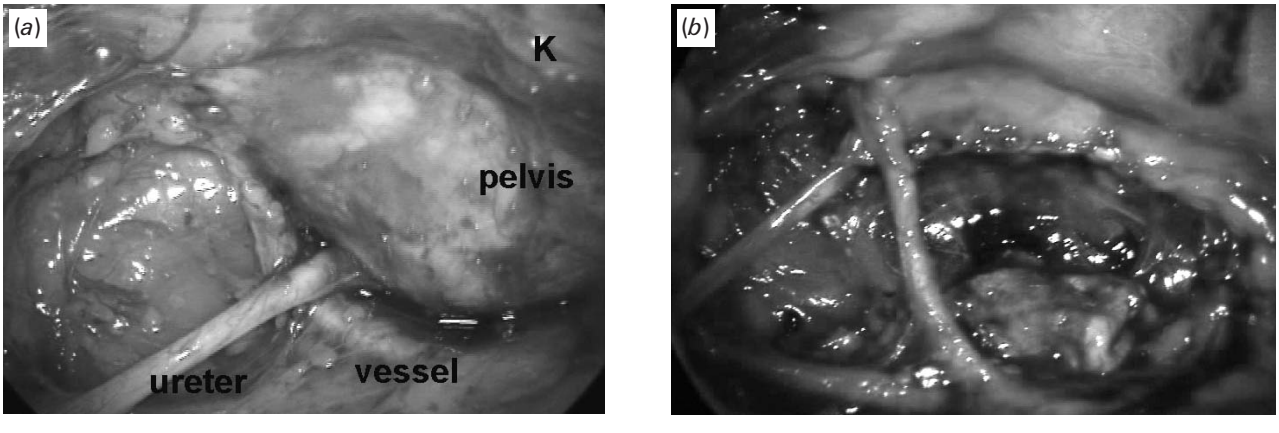

Figure 31.7 Left retroperitoneal pyeloplasty. A 14-year-old boy with left hydronephrosis complicated by hypertension. (*a*) The retroperitoneal laparoscopic exposure identified the aberrant crossing vessel, lying anterior to the ureteropelvic junction (UPJ). K, kidney. (*b*) Dismembered pyeloplasty allowed transposing the UPJ anterior to the vessel, with reduction of the dilated pelvis.

Pyeloplasty should be the best demonstration of the advantage of robot-assisted surgery in overcoming the difficulties encountered during laparoscopic suturing. Craig Peters[37–39] has presented the first preliminary results of robotic-assisted laparoscopic transperitoneal pyeloplasty in children. Olsen and Jorgensen have reported their unique experience on retroperitoneal robotic-assisted pyeloplasty.[40,41] They compared a group of 8 children operated on by the robotic-assisted procedures to a previous group of 15 children operated on by the standard procedure with laparoscopic instruments. The median operative time with the robotic-assisted procedures was lower than with standard equipment (172 minutes vs 210 minutes); the shortest operative time with robotic assistance was 110 minutes. The first impression is that robotic assistance makes suturing easier and may allow extending advanced laparoscopic reconstructive surgery to a larger number of surgeons without previous expertise in advanced laparoscopic surgery. However, in our experience, teaching laparoscopic pyeloplasty was not feasible when the surgeon did not already have an advanced experience in laparoscopy.[42]

Soulie et al[43] have compared retroperitoneal laparoscopic pyeloplasty vs open pyeloplasty with a minimal incision in 53 consecutive non-randomized adults. The mean operating time (165 minutes vs 145 minutes) was similar in both groups. Incidence of complications, hospital stay, and functional results were equivalent for both groups, but the return to painless activity was more rapid with laparoscopy in younger patients. Bauer et al[44] carried out a similar study, with no difference in the postoperative outcome between laparoscopic pyeloplasty and open pyeloplasty. In a recent review, we could not find any comparative study in children.[45] Recently, we have compared retroperitoneal laparoscopic pyeloplasty vs open pyeloplasty in 37 consecutive children.[36] The mean operative time was 96 minutes (range 50–150) and 219 minutes (range 140–310) for the open surgery and the laparoscopy groups, respectively ($p < 0.0001$). Mean hospital stay was 2.4 days (range 1–5) and 5 days (range 3–7) for the laparoscopy and the open surgery groups, respectively ($p < 0.0001$). The use of analgesics was less in the laparoscopy group, but this result needs to be confirmed in a randomized prospective study.

Midterm results confirm that dismembered retroperitoneal laparoscopic pyeloplasty is a safe and feasible approach in children. Although the technique is highly demanding, it has the advantage of duplicating the principles of the gold standard open approach. The transperitoneal approach may be better adapted in young infants, and some experienced laparoscopists prefer a transperitoneal approach in all children. Long operative times may be reduced with experience and possibly with robotic assistance.

Technique of laparoscopic retroperitoneal pyeloplasty[35]

The same access is used, as described for nephrectomy. Yeung et al[34] used different positioning according to the side of the kidney: semiprone for the right side and semilateral for the left side. We currently use a three-trocar technique (see Figure 31.1): the first trocar is 3 or 5 mm for the laparoscope (at the tip of the 12th rib); the second trocar of 3 mm is inserted in the costovertebral angle; and the third trocar of 3 mm is inserted in the top of the iliac crest. The kidney is approached posteriorly and the renal pelvis is first identified. The pyeloureteral junction is identified and a minimal dissection is done to free the junction from connective tissue. Small vessels are divided using bipolar electrocoagulation. Care is taken not to section ureteral blood vessels. A stay stitch is placed at the junction. Aberrant crossing vessels are identified. The renal pelvis is partially divided using scissors at the most dependent part and gentle traction on the stay suture helps to define this point. Keeping the traction, the ureter is partially divided and incised vertically for spatulation. The traction suture helps to mobilize the ureter, so the scissors can be in the axis of the ureter, usually introduced through the last trocar. The anterior surface of the kidney is left adherent to the peritoneum, so that the kidney is retracted medially without the need for individual kidney retraction. The ureteropelvic anastomosis begins using a 6–0 absorbable suture, with a tapered 3/8 circle needle, placed from the most dependent portion of the pelvis to the most inferior point or vertex of the ureteral spatulation. The suture is tied using the intracorporeal technique, with the knots placed outside the lumen. The same stitch is used to run the anterior wall of the anastomosis. The UPJ is kept intact for traction and stabilization of the suture line, and removed just before tying the last suture on the pelvis. This stay suture may be fixed to the psoas muscle to give stability and to facilitate the suturing. A double-pigtail stent is inserted through the costovertebral angle trocar, and if there is doubt, its position in the bladder is assured under fluoroscopy. The posterior ureteropelvic anastomosis is then performed. To avoid a second general anesthesia to remove the stent,

we are currently inserting a transanastomotic pyelostomy stent. The stent is closed on the first postoperative day and removed at 1 week in the outpatient clinic. We still proceed with double-pigtail stent in the cases with intrarenal pelvis because of the technical difficulties associated with the pyelostomy stent in these cases. The pelvis is trimmed if needed. In cases of aberrant crossing vessels (see Figure 31.7), the technique is slightly different. After placement of the stay suture, the ureter is completely divided and the UPJ and the pelvis are delivered anterior to the vessels with the help of the stay suture; then the anastomosis is performed as described. A Foley catheter is left in the bladder for 24 hours postoperatively.

Technique of laparoscopic transperitoneal pyeloplasty

The same approach is used as described for the nephrectomy. Steps of the pyeloplasty are identical to the retroperitoneal approach. A traction suture may be inserted through the anterior abdominal wall to stabilize the suture line.

We have used the transperitoneal approach only in cases of UPJ obstruction in a horseshoe kidney. The anterior position of the UPJ in this specific anatomic variant makes it easier using the anterior transperitoneal approach.

Wilms' tumor

32

Michael L Ritchey and Fernando A Ferrer

Introduction

Nephroblastoma, or Wilms' tumor, is an embryonal tumor that develops from remnants of immature kidney. It is the most common renal tumor of childhood. Current survival of children with Wilms' tumor is excellent, and emphasis is now on reducing the morbidity of treatment for low-risk patients. Unfortunately, there is still a subset of high-risk patients with poor survival for whom new treatment strategies are needed. This chapter reviews the epidemiology, pathology, and recent advances in the understanding of the biology of Wilms' tumor. The current management of children with all stages of nephroblastoma is discussed in detail.

Epidemiology

The overall annual incidence of Wilms' tumor is approximately 7.6 cases per million children under 15 years of age, or about 500 new cases annually in the United States. Wilms' tumor accounts for 6–7% of all childhood cancers.[1,2] It typically affects young children (median age 3.5 years), although older children and occasionally even adults can be affected. Wilms' tumor occurs at an earlier median age in children with bilateral tumors, 29.5 months for boys and 32.6 months for girls. The disease occurs nearly equally in girls and boys worldwide, but the frequency is slightly higher among girls in the United States.[3]

Children with Wilms' tumor frequently have associated congenital anomalies or recognizable syndromes. Syndromes associated with a predisposition to develop Wilms' tumor may be divided into those characterized by overgrowth and those lacking overgrowth. Syndromes with overgrowth features include hemihypertrophy, which may occur alone or as part of the Beckwith–Wiedemann syndrome (BWS). BWS is a rare disorder consisting of developmental anomalies characterized by excess growth at the cellular, organ (macroglossia, nephromegaly, hepatomegaly), or body segment (hemihypertrophy) levels.[4,5] The incidence of tumor development in BWS is 10–20%, including Wilms' tumor, adrenocortical neoplasms, and hepatoblastoma. The risk of Wilms' tumor development in patients with hemihypertrophy and BWS is estimated to be in the order of 4–10%,[5–8] with 21% of those children presenting with bilateral disease.[9] Data from the BWS registry suggest that nephromegaly is a strong risk factor for the subsequent development of Wilms' tumor.[10] The mean age at diagnosis of Wilms' tumor in hemihypertrophy patients is similar to that of the general Wilms' tumor population.[11] Other overgrowth syndromes, such as the Perlman and the Simpson–Golabi–Behmel syndromes, are also associated with the development of Wilms' tumor.[12,13]

Genitourinary anomalies (hypospadias, cryptorchidism, renal fusion anomalies) are present in 4.5% of patients with Wilms' tumor.[14] One specific association of male pseudohermaphroditism, renal mesangial sclerosis, and nephroblastoma is the Denys–Drash syndrome.[15,16] Although the classic presentation is that of ambiguous genitalia, up to 40% of children appear phenotypically female.[17] Genetic studies indicate that Denys–Drash syndrome is associated with mutations of the 11p13 Wilms' tumor gene.[16] Roughly 1% of Wilms' tumor patients are diagnosed with the WAGR (Wilms' tumor, aniridia, genital anomalies, and mental retardation) syndrome.[18] Most affected individuals have a constitutional deletion on chromosome 11 and the incidence of Wilms' tumor formation in these children is 42%. Children with WAGR present at an earlier age, have lower birth weights, and an increased incidence

of bilateral disease.[19] Wilms' tumors have been reported in association with neurofibromatosis, Sotos's syndrome, and Klippel–Trénaunay–Weber syndrome.[20]

There is an increased risk of Müllerian duct anomalies in girls with Wilms' tumor.[21] Approximately 10% of girls will have abnormalities such as duplication of the cervix or uterus, or bicornuate uterus. Patients with horseshoe kidney have been noted to develop Wilms' tumor at a higher than expected rate.[22,23] Wilms' tumor has been reported in patients with multicystic dysplastic kidney, but there is not sufficient evidence that this occurs at an incidence greater than for children with two normal kidneys.[24,25]

Periodic imaging with renal ultrasound has been recommended in children with hemihypertrophy, BWS, and aniridia, with the hope that the tumor will be discovered at an earlier stage. A review of BWS patients reported to the National Wilms' Tumor Study Group (NWTSG) has found more stage I tumors,[9] and high-risk children undergoing periodic screening have more stage I tumors and small tumor diameters.[26] There were not enough patients in these retrospective reviews to determine if early detection had an impact on patient survival. Craft et al reported on 13 high-risk children undergoing screening with abdominal ultrasound and did not find any significant difference in stage distribution compared with children not undergoing screening.[27] The recommended screening interval is every 3–4 months.[28,29] Not all new lesions are Wilms' tumor, as there is an increased incidence of non-malignant renal lesions in children with BWS.[30,31] Nephrectomy has been performed for benign disease due to false-positive screening.

Biology and genetics

The role of genetic alterations in Wilms' tumor development has been intensely studied. Most Wilms' tumors arise from somatic mutations. These mutations are present in the tumor tissue only and cannot be transmitted to the progeny of the affected individual. A much smaller percentage of Wilms' tumors (~10%) appear to be the result of germline mutations. These mutations arise in the actual germ cells of the patient and can be inherited, although in some cases they can occur de novo. Patients with germ cell mutations are characterized by syndromic conditions, associated congenital anomalies, family history of tumor, and tumors that occur at an earlier age.[32] It was this group of patients that prompted Knudson to suggest that his 'two-hit' theory, originally developed by studying children with retinoblastoma, might also apply to Wilms' tumor.[33,34]

The Knudson model predicts that two genetic events are required for tumor formation.[33] Individuals with a genetic predisposition carry an initial lesion in their germline, either inherited from a parent or resulting from a de-novo germline mutation. In these individuals, all body cells have already been affected by the first event. Consequently, only one new event in any one cell is required for tumor development. By contrast, in individuals that are not genetically predisposed (sporadic cases), two relatively rare independent events are required in the same cell. Subsequent genetic studies in a number of tumors have confirmed the Knudson model, demonstrating that the two postulated 'genetic hits' constitute the inactivation of both alleles of a tumor suppressor gene.[35] The clearest example of tumorigenesis following the inactivation of both copies of a single tumor suppressor gene is the development of retinoblastoma following the inactivation of the retinoblastoma gene *RB1*. By contrast, the 'two-hit' theory which was so elegantly confirmed in patients with retinoblastoma, has not stood the test of time in Wilms' tumor. Today it is recognized that the biologic pathways leading to the development of the majority of Wilms' tumor are complex and probably involve several genetic loci.[32,34]

Observation that patients with aniridia, genital anomalies, and mental retardation were at a high risk for Wilms' tumor led to cytogenetic studies that identified a heterozygous deletion at band 11p13 of chromosome 11. Using cloning techniques, the *WT1* gene was identified.[36–38] Chromosome 11p13 encompasses various genes, including *PAX6*, abnormalities of which can be responsible for aniridia.[39] *WT1* is expressed in the normal developing kidney and abnormally expressed in some Wilms' tumor specimens. *WT1* encodes a zinc finger transcription factor that is thought to function as a classic tumor suppressor gene. A partial list of genes that are targets of *WT1* regulation include *EGFR*, *PDGF*, *IGF*, *N-Myc*, *PAX 2*, *MDR-1*, and *P-21*, all notable for their association with tumorgenesis.[40] *WT1* mutations have been shown to occur in human DNA from sporadic Wilms' tumor, as well as the germline of patients with a genetic predisposition to cancer.

Although at first, *WT1* was considered a classic tumor suppressor gene, i.e. loss of both copies of the gene are required for tumor development, it has now become clear that specific alterations in only one of

the two *WT1* alleles may contribute to abnormal cell growth and associated genitourinary abnormalities.[35] Normal function of *WT1* is necessary for genitourinary development. Mutations at the *WT1* locus, particularly in males, may confer extensive genitourinary defects, most notably male pseudohermaphroditism.[16,41] The affected gonads and kidneys in patients with the Denys–Drash syndrome are heterozygous for germline mutations. Denys–Drash syndrome, characterized by pseudohermaphroditism, renal failure, and Wilms' tumor, is the result of point mutations in the binding domain of *WT1*.[16] The resulting phenotype is far more severe than that observed in children with a constitutional deletion of one *WT1* allele (i.e. WAGR patients) and suggests that the mutated protein can inhibit the activity of the wild-type protein, resulting in a 'dominant negative' effect.[42] A spectrum of phenotypes can be demonstrated by patients with the Denys–Drash syndrome, depending on the type of *WT1* mutation.[32] Interestingly, renal dysfunction once thought to be limited to those with Denys–Drash syndrome, is now known to occur years after treatment in patients with WAGR syndrome.[19]

In addition to WAGR and Denys–Drash patients, germline mutations have also been found in familial Wilms' tumor. Families harboring a constitutional *WT1* abnormality constitute only a small percentage of the reported affected pedigrees.[43] Germline *WT1* mutation has been correlated with a predominantly stromal pathology.[44] Constitutional mutations of *WT1* are rarely seen in patients with non-syndromic, unilateral tumors in the absence of genitourinary abnormalities.[43]

In summary, the majority of Wilms' tumors do not have genetic alterations at chromosome 11p13. Germline *WT1* mutations are associated with genitourinary anomalies. No increased risk of mutation is found in patients with nephrogenic rests, bilateral Wilms' tumor, or a family history of Wilms' tumor.[45]

A second potential Wilms' tumor gene, *WT2*, has been identified on chromosome 11p15, based on the observation of loss of heterozygosity at this site,[46,47] but the actual gene responsible remains to be determined. Much like the association between *WT1* at chromosome 11p13 and the WAGR syndrome, *WT2* has been linked to the BWS.[46,48] BWS is an overgrowth disorder that is associated with a 5–10% risk of Wilms' tumor.[46] Recent studies suggest that abnormal expression of embryonal growth factor encoded by the insulin-like growth factor-2 gene (*IGF2*) is involved in the pathophysiology of BWS.[49]

Loss of heterozygosity at chromosomes 16q (present in 20% of all Wilms' tumors) or 1p (seen in 10% of tumors) has been suggested to be a predictor of poor outcome in children with Wilms' tumor.[50–52] However, the prognostic significance of these features has been questioned.[53]

Abnormalities of chromosome 7p have been reported in patients with Wilms' tumor. Cytogenetic analysis of individuals with constitutional deletions in chromosome 7p who have demonstrated a loss of the second allele in tumor tissues suggests that this may be the site of another, as yet unidentified, tumor suppressor gene.[54] Alterations of the *p53* tumor suppressor gene located on chromosome 17p have been noted in approximately 75% of anaplastic tumors, suggesting an important role in the development of anaplasia.[55,56] By acting as a down-regulator of cell proliferation, and a positive regulator of cellular apoptosis, *p53* is known to play a significant role in tumor suppression. Malkin et al suggested that the absence of *p53* is an indicator of advanced disease in Wilms' tumor, regardless of the presence of anaplastic changes.[57] Monosomy at chromosome 22 has also been linked to the biology of Wilms' tumor. Bown et al have reported a significant decrease in tumor-free survival at 5 years in patients demonstrating monosomy of chromosome 22.[53]

Histopathology

Wilms' tumor usually compresses the adjacent normal renal parenchyma, forming a pseudocapsule composed of compressed, atrophic renal tissues. This intrarenal pseudocapsule can be helpful to distinguish Wilms' tumor from other renal tumors. Most tumors are soft and friable, with necrotic or hemorrhagic areas frequently noted. This consistency increases the chance of intraoperative tumor rupture that can predispose to local tumor recurrence. Wilms' tumor is characterized by tremendous histologic diversity. The classic triphasic pattern includes varying proportions of three cell types: blastemal, stromal, and epithelial. The proportion of each of these components varies, with some tumors consisting of only biphasic or even monomorphous patterns. These different components respond differently to treatment, which can have an impact on outcome (see below discussion under preoperative chemotherapy).[58] In addition to expressing a variety of cell types found in a normal developing kidney, Wilms' tumor often contains tissues such as skeletal muscle, cartilage, and squamous

epithelium. These heterotopic cell types probably reflect the primitive developmental potentials of metanephric blastema that are not expressed in normal nephrogenesis. Most Wilms' tumors are unicentric, but 12% are multicentric unilateral tumors.[11] Extrarenal locations are rare and are thought to arise from displaced metanephric elements or mesonephric remnants.

One important observation was the identification of tumors with *unfavorable* histologic features that were associated with increased rates of relapse and death.[59] These unfavorable features occurred in approximately 10% of patients, but accounted for almost half of the tumor deaths in early NWTSG studies.[60] Anaplasia is defined by the presence of gigantic polyploid nuclei within the tumor sample. It is rare in the first 2 years of life but the incidence increases to 13% in children ≥ 5 years old.[61] Anaplasia is a feature of Wilms' tumor that is clearly associated with resistance to chemotherapy. There has been a similar incidence of anaplasia in the NWTSG study (5%) and in the International Society of Pediatric Oncology (SIOP) study (5.3%).[62] Anaplasia has been further divided into focal and diffuse patterns to reflect the different prognosis of anaplasia that is present throughout the kidney or in an extrarenal location. Focal anaplasia requires that cells with anaplastic nuclear changes be confined to sharply restricted foci within the primary tumor.[63] Diffuse anaplasia is diagnosed when anaplasia is present in more than one portion of the tumor or is found in any extrarenal or metastatic site. When the anaplastic component is completely removed (stage I), the outcome is generally excellent.[64] This suggests that anaplasia is more a marker of chemoresistance than inherent aggressiveness of the tumor. When anaplastic changes are not present, the tumor is referred to as being of favorable histology (FH) because of the generally good outcome for these patients.[65] Clear cell sarcoma of the kidney (CCSK) and rhabdoid tumor of the kidney (RTK) were previously grouped as unfavorable histology Wilms' tumors. They are now recognized as separate malignant entities (see below).[66,67]

More than one-third of kidneys resected for Wilms' tumor contain precursor lesions, known as nephrogenic rests.[68] Nephrogenic rests represent the abnormal persistence into postnatal life of embryonal cells that can produce a malignancy (Figure 32.1). Two distinct categories of nephrogenic rests exist, based on the position of these lesions within the renal lobe. Perilobar nephrogenic rests (PLNRs) are confined to the periphery of the renal lobe. Intralobar nephrogenic rests (ILNRs) occur anywhere in the kidney, including the renal sinus and collecting system. There are biologic differences distinguishing PLNR from ILNR (Table 32.1). Nephrogenic rests have a varied life and most do not form Wilms' tumor. A rest can undergo maturation, sclerosis, involution, and complete disappearance. PLNRs have been detected in 1% of kidneys in infants on postmortem examination; most of these rests apparently undergo involution.[69] ILNR can become cystic and be indistinguishable from renal dysplasia.

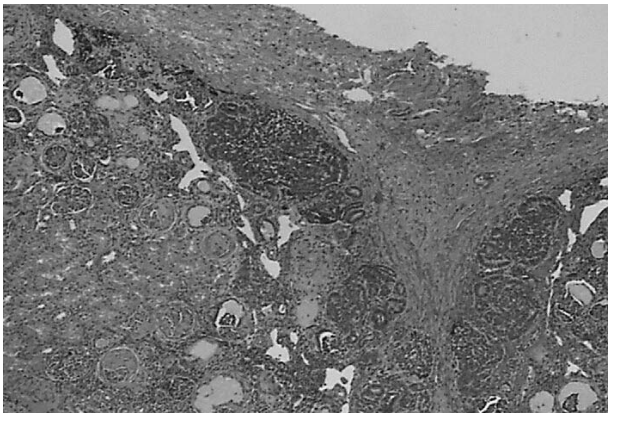

Figure 32.1 Perilobar nephrogenic rest composed of blastemal cells just beneath the renal capsule (hematoxylin and eosin, ×40).

Hyperplastic nephrogenic rests can produce a renal mass easily mistaken for a small Wilms' tumor.[69] Biopsy of a hyperplastic rest is of little value in distinguishing this lesion from a Wilms' tumor unless the interface between the rest and normal kidney is

Table 32.1 Clinical features of ILNR and PLNR

	ILNR	PLNR
Associated syndromes	WAGR Denys–Drash Genitourinary anomalies	BWS Hemihypertrophy Perlman
Median age of Wilms' tumor development	23 months	36 months
Wilms' tumor histology	Stroma predominant	Blastema, epithelial predominant

WAGR = Wilms' tumor, aniridia, genitourinary, and retardation; BWS = Beckwith–Wiedemann syndrome; ILNR = intralobar nephrogenic rest; PLNR = perilobar nephrogenic rest.

included. Wilms' tumor will have a pseudocapsule at the interface, with the normal parenchyma compressing the normal elements. Neoplastic induction of cells of a nephrogenic rest can produce Wilms' tumor and possibly other benign or malignant renal neoplasms. The Wilms' tumor will have a spherical shape, whereas hyperplasic rests will be more elliptical or lenticular in shape. Magnetic resonance imaging (MRI) may be of some value in distinguishing between the two lesions, but this needs to be confirmed prospectively in large numbers of patients.[70]

The presence of multiple or diffuse nephrogenic rests will lead to the diagnosis of nephroblastomatosis. The term nephroblastomatosis was originally used to describe massive bilateral nephromegaly in which the reniform shape was preserved.[71] Nephroblastomatosis can be subclassified according to the rest categories present: e.g. diffuse hyperplastic PLNRs, in which the majority of the cortical surface of one or both kidneys is composed of hyperplastic nephrogenic rests. The entire nephrogenic zone is involved, with a thick rind capping the entire kidney. These patients are prone to Wilms' tumor development and bilateral lesions are common. Perlman et al have reviewed 52 cases of diffuse hyperplastic PLNRs reported to the NWTSG pathology center.[72] Wilms' tumor developed in 23 patients at a median of 30 months. Of children receiving adjuvant therapy at diagnosis, 17/33 (52%) developed a Wilms' tumor.

Multiple rests in one kidney usually implies that nephrogenic rests are present in the other kidney.[68] Children younger than 12 months diagnosed with Wilms' tumor who also have nephrogenic rests have a markedly increased risk of developing contralateral disease.[73] They need regular imaging surveillance to detect contralateral recurrence.[74] The occurrence of metachronous Wilms' tumor in patients previously treated with conventional chemotherapeutic regimens suggests that nephrogenic rests are not always eradicated.

Presentation, preoperative evaluation, and staging

Most children with Wilms' tumor present with an asymptomatic abdominal mass. Other signs and symptoms at diagnosis are abdominal pain, gross hematuria, and fever. Occasionally, a child will present with an acute abdomen due to tumor rupture, with hemorrhage into the peritoneal cavity. Other atypical presentations may result from compression or invasion of adjacent structures: e.g. extension of the tumor into the renal vein and inferior vena cava (IVC). Varicocele, hepatomegaly due to hepatic vein obstruction, ascites, and congestive heart failure are found in fewer than 10% of patients with intracaval or atrial tumor extension.[75] Hypertension is present in 25% of cases and has been attributed to elevated plasma renin levels.[76] During the physical examination, it is important to note any physical findings of associated Wilms' tumor syndromes such as aniridia, hemihypertrophy, and genitourinary anomalies.

The preoperative evaluation can generally be completed in 48 hours. Emergent operation is not necessary unless there is evidence of active bleeding or tumor rupture. Laboratory evaluation should include a complete peripheral blood count, platelet count, renal function tests, liver function tests, serum calcium, and urinalysis. Elevation of the serum calcium can occur in children with congenital mesoblastic nephroma and RTK. Acquired von Willebrand's disease has been found in 8% of newly diagnosed Wilms' tumor patients.[77]

The preoperative imaging evaluation of children with a solid abdominal mass has evolved over the years. The first study obtained is often a renal ultrasound that can determine if the mass is predominantly solid or cystic. Contrast-enhanced computed tomography (CT) or MRI of the abdomen is obtained next. All of the solid renal tumors of childhood have similar radiographic features. However, defining the exact histology is not as important as establishing that there is a solid renal tumor present, which will help the surgeon plan for a major cancer operation.[78] Another important role of imaging studies is to establish the presence of a functioning contralateral kidney prior to nephrectomy.

The radiologist should exclude intracaval tumor extension, which occurs in 4% of Wilms' tumor patients (Figure 32.2).[75] This can usually be excluded on ultrasound, but MRI is the study of choice if extension of tumor into the IVC cannot be excluded by ultrasound.[79]

There is some controversy regarding the utility of preoperative imaging for tumor staging.[74,80,81] Accurate staging of children with Wilms' tumors is essential to define tumor extent prior to initiating treatment, as outcome is highly correlated with stage.[82] However, the staging system used in NWTSG studies relies on surgical findings and pathologic examination (Table 32.2). It would be a great asset if imaging provided reliable information regarding local extension of tumor beyond the renal capsule

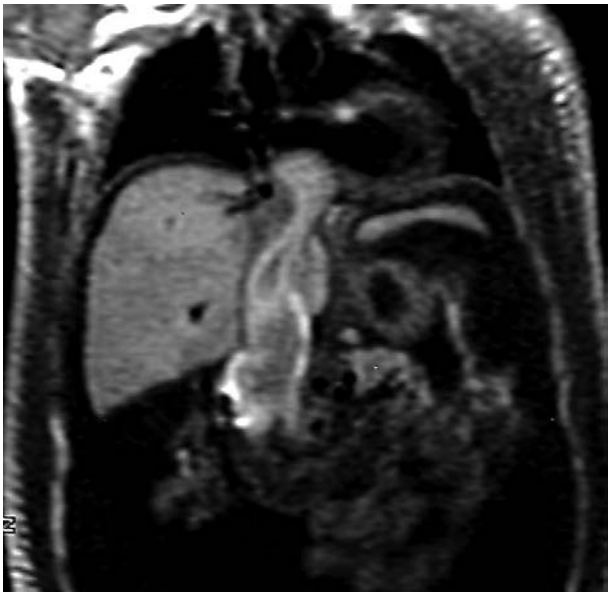

Figure 32.2 Magnetic resonance imaging scan demonstrating tumor extension into the inferior vena cava.

Table 32.2 NWTS-5 staging system for Wilms' tumor

Stage I: The tumor is limited to the kidney and was completely excised. The renal capsule has an intact outer surface. The tumor was not ruptured or biopsied prior to removal (fine-needle aspiration biopsies are excluded from this restriction). The vessels of the renal sinus are not involved. There is no evidence of tumor at or beyond the margins of resection.

Stage II: The tumor extends beyond the kidney, but was completely excised. There may be regional extension of tumor (i.e. penetration of the renal capsule or extensive invasion of the renal sinus). The blood vessels outside the renal parenchyma, including those of the renal sinus, may contain tumor. The tumor was biopsied (except for fine-needle aspiration), or there was spillage of tumor before or during surgery that is confined to the flank, and does not involve the peritoneal surface. There must be no evidence of tumor at or beyond the margins of resection.

Stage III: Residual non-hematogenous tumor is present, and confined to the abdomen. Any one of the following may occur: (1) Lymph nodes within the abdomen or pelvis are found to be involved by tumor (renal hilar, para-aortic, or beyond). (Lymph node involvement in the thorax, or other extra-abdominal sites would be a criterion for stage IV.) (2) The tumor has penetrated through the peritoneal surface. (3) Tumor implants are found on the peritoneal surface. (4) Gross or microscopic tumor remains postoperatively (e.g. tumor cells are found at the margin of surgical resection on microscopic examination). (5) The tumor is not completely resectable because of local infiltration into vital structures. (6) Tumor spill not confined to the flank occurred either before or during surgery.

Stage IV: Hematogenous metastases (lung, liver, bone, brain, etc.), or lymph node metastases outside the abdominopelvic region are present.

Stage V: Bilateral renal involvement is present at diagnosis. An attempt should be made to stage each side according to the above criteria on the basis of the extent of disease prior to biopsy or treatment.

or into regional lymph nodes. The local tumor burden (e.g. regional lymph node involvement) determines the intensity of the chemotherapy regimen and whether a child receives abdominal irradiation. However, prospective correlation with pathologic findings has not been done. Preoperative CT can certainly identify regional adenopathy, but enlarged benign retroperitoneal lymph nodes are common in children. Correlation between pathologic findings and lymph node evaluation at surgical exploration in Wilms' tumor patients has found high false-positive and false-negative error rates.[83] It is unlikely that CT or MRI will be more accurate than surgical inspection of the regional lymph nodes.

Detection of extrarenal tumor extension into the perirenal fat and into adjacent structures is also problematic. Most children identified as having possible invasion of the liver on CT are found at the time of surgical exploration to have hepatic compression, rather than hepatic invasion.[84] Therefore, determination of inoperability must be made at surgical exploration. Non-opacification of the kidney on CT may result from tumor obstruction of the collecting system,[85] complete replacement of the renal parenchyma with neoplasm, or intravascular tumor extension.[75] Plain chest radiographs may be obtained to determine whether pulmonary metastases are present. However, most centers obtain a CT of the chest in the initial evaluation of children with Wilms' tumor. This can detect small lesions missed on chest X-ray, although the management of such lesions is debated.[86,87] Additional imaging studies are helpful under specific conditions. For example, a radionuclide bone scan and X-ray skeletal survey should be obtained postoperatively on all children with CCSK.[88] Brain imaging, using MRI or CT, should be

obtained on all children with CCSK or with RTK, as both are associated with intracranial metastases.[89]

The NWTSG has long recommended formal exploration of the contralateral kidney in all children undergoing nephrectomy for presumed unilateral Wilms' tumor. This has been considered necessary to identify lesions that might be missed on preoperative imaging. If lesions are identified intraoperatively, biopsy alone of the lesions is advised and definitive surgical resection is deferred (for both kidneys). Review of NWTS-4 patients with bilateral Wilms' tumor found that 7% of lesions were missed on preoperative imaging studies.[90] Most lesions were managed with biopsy alone, yet extended follow-up of the children has not demonstrated any relapses.[91] The majority of these children had nephrectomy of the more involved kidney at diagnosis before exploration of the contralateral kidney. This was also noted in a recent report of NWTS-5 patients.[92] The conclusion of the latest report was that routine exploration is not necessary, provided that preoperative imaging with thin slices on multidetector helical CT scanners or MRI is performed.[91]

Surgery

The surgeon has an important role in the management of a child with Wilms' tumor. Careful removal of the tumor without rupture or spill is mandatory to decrease the risk of local abdominal relapse.[93] Complete tumor resection also improves patient survival. Another important surgical objective is determining tumor extent. As noted above, staging of the tumor is surgical. A transperitoneal approach is preferred to allow thorough exploration of the abdominal cavity. Exploration of the contralateral kidney is no longer mandated prior to nephrectomy if the preoperative CT or MRI demonstrate a normal kidney.[91] If exploration is needed, the colon is reflected and Gerota's fascia opened so that the kidney can be inspected on all surfaces. Any abnormalities of the kidney should be biopsied to exclude Wilms' tumor or nephrogenic rests.

Palpation of the renal vein and IVC should be performed to exclude intravascular tumor extension prior to vessel ligation. Radical nephrectomy is performed with partial ureterectomy. Formal lymph node dissection is not required but lymph node sampling is an integral step during surgery for Wilms' tumor.[83] Lymph node metastases (stage III) have an adverse outcome on survival. Failure to sample lymph nodes has been identified as a risk factor for local relapse in stage I patients, suggesting inadequate staging.[93]

One should not overlook the morbidity of surgery that can produce both acute and late complications. A review of NWTS-4 patients undergoing primary nephrectomy found an 11% incidence of surgical complications.[94] The most common complications were hemorrhage and small bowel obstruction. Risk factors associated with increased surgical complications are higher local tumor stage, intravascular extension, en bloc resection of other visceral organs, and incorrect preoperative diagnosis.[78]

Treatment and outcome

The development of effective systemic chemotherapy in the 1960s rapidly changed the outcome and approach to treatment of Wilms' tumor.[95] Randomized clinical trials have been conducted by NWTSG, SIOP, and the United Kingdom Children's Cancer Study Group (UKCCSG) to determine the appropriate role for each of the therapeutic modalities available. Patients are stratified into different treatment groups based on extent of disease and histopathologic features. The goals of these trials are to allow a reduction in the intensity of therapy for most patients, while maintaining overall survival, and to decrease potential late sequelae. For example, radiation therapy (XRT), once administered routinely to all children, is now reserved for those with advanced stage disease or specific adverse prognostic features.

National Wilms' Tumor Study Group

The first two NWTSG studies, NWTS-1 (1969–1973) and NWTS-2 (1974–1978), showed that postoperative local irradiation was unnecessary for group I patients.[96,97] The combination of vincristine (VCR) and dactinomycin (AMD) was noted to be more effective than the use of either drug alone, and the addition of doxorubicin (DOX) improved survival for higher-stage patients. Important findings of NWTS-1 and -2 were identification of unfavorable histologic features and other prognostic factors that allowed refinement of the staging system, stratifying patients into high-risk and low-risk treatment groups.[98] It was recognized that the presence of lymph node metastases had an adverse outcome on survival.[96,97] Children with lymph node metastases as well as those with diffuse tumor spill were found to be at increased risk of abdominal relapse. Therefore,

such patients were from then on classified as having stage III disease and given whole abdominal irradiation.[82] These findings were incorporated into the design of NWTS-3 to try and decrease the intensity of therapy for the majority of low-risk patients.

In NWTS-3 (1979–1986), patients with stage I, FH Wilms' tumor were treated successfully with either a 10- or 18-week regimen of VCR and AMD.[82] This considerably decreased the amount of chemotherapy administered and the total duration of treatment. The 4-year relapse-free survival was 89%, and the overall survival was 95.6%. Stage II FH patients treated with AMD and VCR without postoperative XRT had an equivalent survival (4-year overall survival of 91.1%) to patients who received the same treatment plus DOX with or without XRT. This demonstrated that the cardiotoxic drug DOX is not necessary for the successful treatment of this group of patients. This also demonstrated that XRT could now be omitted for the majority of children with Wilms' tumor. For stage III FH patients, 10.8 Gy of abdominal irradiation was shown to be as effective as 20 Gy in preventing abdominal relapse if DOX was added to VCR and AMD. The 4-year relapse-free survival for stage III patients was 82% in NWTS-3 and the 4-year overall survival was 90.9%. Patients with stage IV FH tumors received abdominal (local) irradiation based on the local tumor stage. In addition, they all received 12 Gy to both lungs. In combination with VCR, AMD, and DOX, the 4-year relapse-free survival was 79% and the overall survival was 80.9%. There was no statistically significant improvement in survival when cyclophosphamide was added to the three-drug regimen.

The goals of NWTS-4 (1986–1994) were to continue improving treatment results while decreasing the cost of therapy through modification of the schedule of drug administration. 'Pulse-intensive' chemotherapy regimens, employing single doses of AMD and DOX, were compared with regimens using divided doses of the drugs. Pulse-intensive regimens utilized simultaneous administration of agents at less frequent intervals to decrease the number of clinic visits and hence the cost of cancer treatment. In addition, treatment durations of approximately 6 and 15 months were compared in patients with stages II–IV FH tumors. NWTS-4 demonstrated that, while the administered drug dose–intensity was greater on pulse-intensive regimens, these regimens produce less hematologic toxicity than the standard regimens.[99] Patients treated with pulse-intensive regimens achieved equivalent survival compared with those treated with standard chemotherapy regimens.[100] Treatment with 6 months of chemotherapy was as effective as 15 months.

Children with anaplastic Wilms' tumors were randomized in NWTS-3 and NWTS-4 to receive VCR, AMD, DOX, or those three drugs with the addition of cyclophosphamide. The results were analyzed after the tumors were reclassified using the criteria of Faria et al.[63] There was no difference in outcome between the regimens for children with focal anaplasia, who had a prognosis similar to that for favorable histology patients.[101] For stage II–IV diffuse anaplasia, the addition of cyclophosphamide to the three-drug regimen improved the 4-year relapse-free survival (27.2% vs 54.8%).

Treatment recommendations used in NWTS-5 (1995–2003) are outlined in Table 32.3. Treatment of patients with stage I or II FH tumors, and stage I anaplastic Wilms' tumor was the same. They received a pulse-intensive regimen of VCR and AMD for 18 weeks. Patients with stage III FH and stage II–III focal anaplasia were treated with AMD, VCR, and DOX, and 10.8 Gy XRT. Patients with stage IV FH tumors received abdominal irradiation based on the local tumor stage and 12 Gy to both lungs.

NWTS-5 was a single-arm therapeutic trial without any randomization for therapy. Prospective collection of information regarding biologic features of the tumors was part of this study. A collection of banked tumor specimens is available to evaluate new prognostic factors that may be identified in the future. Most importantly, the clinical outcome is available for patients for whom there are banked specimens. One of the primary goals of the study was to verify the preliminary findings that loss of heterozygosity (LOH) for chromosomes 16q and 1p is useful in identifying patients at increased risk for relapse and death.[51] Among patients with stage I–II FH tumors, the relative risk (RR) of relapse and death were increased for LOH 1p only (RR = 2.2 for relapse; RR = 4.0 for death), for LOH 16q only (RR = 1.9 and RR = 1.4), and for LOH for both regions (RR = 2.9 and RR = 4.3) in comparison with patients lacking LOH at either locus.[52] The risks of relapse and death for patients with stage III–IV FH tumors were increased only with LOH for both regions (RR = 2.4 and RR = 2.7). These results demonstrate that LOH for these chromosomal regions can now be used as an independent prognostic factor, together with disease stage, to target intensity of treatment to risk of treatment failure.

A unique aspect of the NWTS-5 trial was that a select group of patients <2 years of age with stage I

Table 32.3 Treatment schema used in National Wilms' Tumor Study-5

	Radiotherapy	Chemotherapy[a]
Stage I and II, favorable histology	None	Regimen EE-4A
Stage I focal or diffuse anaplasia		
Stage I, favorable histology, age <2 years, tumor weight <550 g	None	Regimen EE-4A
Stage III and IV, favorable histology	Yes	Regimen DD-4A
Stage II–IV, focal anaplasia		
Stage II–IV, diffuse anaplasia	Yes	Regimen I
Stage I–IV clear cell sarcoma of the kidney		
Stage I–IV rhabdoid tumor of the kidney	Yes	Regimen RTK

[a] 1998 modification to original protocol:
- Regimen EE-4A: pulse-intensive dactinomycin, vincristine (18 weeks)
- Regimen DD-4A: pulse-intensive dactinomycin, vincristine, doxorubicin (24 weeks)
- Regimen I: dactinomycin, vincristine, doxorubicin, cyclophosphamide, and etoposide (24 weeks)
- Regimen RTK: carboplatin, etoposide and cyclophosphamide (24 weeks)
- Stage IV/FH patients are given radiation based on the local tumor stage.

FH tumors, weighing <550 g, were managed with surgery alone. This was based on preliminary observation of favorable outcomes on small numbers of such patients when postoperative adjuvant therapy had been omitted.[102] Also a review of NWTSG patients had found excellent outcomes for such patients, albeit with postoperative chemotherapy.[103] This portion of the study was closed when the number of tumor relapses exceeded the limit allowed by the design of the study. However, the 2-year overall survival of this cohort was 100% due to the high rate of retrieval of the relapsed patients.[104] These results suggest that such an approach should continue to be evaluated in future trials.

International Society of Pediatric Oncology

The clinical protocols conducted by SIOP differ from the NWTSG in that therapy is given before surgery. This approach usually results in tumor shrinkage, reducing the risk of intraoperative rupture or spill.[105] It is also postulated that the neoadjuvant therapy will treat micrometastases, leading to a more favorable stage distribution at the time of surgery. A greater number of patients have 'postchemotherapy stage I' tumors. This postchemotherapy stage is used to stratify patients for treatment.

The first two SIOP studies answered questions with regard to the use of prenephrectomy XRT.[105] The third SIOP study, SIOP-5, showed that 4 weeks of AMD and VCR was as effective as prenephrectomy XRT in avoiding surgical tumor rupture and increasing the proportion of patients with low-stage disease.[106] SIOP-6, the fourth SIOP study on Wilms' tumor, demonstrated that patients with postnephrectomy stage I disease can safely be treated with 18 weeks of AMD and VCR.[107] Those patients with stage II lymph node-negative disease, however, were shown to have a higher rate of relapse if postoperative abdominal irradiation was omitted. It was concluded that these children require more intensive postnephrectomy chemotherapy, including the use of an anthracycline.[107] Finally, SIOP-6 confirmed the need for a three-drug chemotherapy regimen following nephrectomy for those with more advanced stage disease, i.e. stage II lymph node positive and stage III.

The fifth SIOP Wilms' tumor trial, SIOP-9 (1987–1991), evaluated the duration of prenephrectomy chemotherapy. The number of postchemotherapy stage I was similar after either 4 or 8 weeks of therapy (64% vs 62%) and 2-year event-free survival (EFS) was equivalent.[108] Also, there was no significant additional tumor shrinkage benefit after 4 weeks of preoperative chemotherapy.[108] Children with stage IIN0 disease were treated with VCR, AMD, and an anthracycline for 27 weeks without XRT, whereas children with IIN1 and III disease were given the same regimen and abdominal irradiation. The 2-year EFS and overall survival (OS) for stage IIN0 was

84% and 88% and for stage IINI and III was 71% and 85%, respectively. There were 59 children with stage I–IV tumors who had complete tumor necrosis induced by chemotherapy, and 98% of these children had no evidence of disease at 5 years.[109] The latest SIOP study on Wilms' tumor, SIOP 93–01 (1993–2000), evaluated a reduction in postoperative therapy for patients with stage I intermediate risk and anaplastic Wilms' tumor.[110] Patients were randomized to receive either 4 or 18 weeks of postoperative chemotherapy with AMD and VCR. Two-year EFS was 91.4% after 4 weeks and 88.8% after 18 weeks of therapy, demonstrating that survival can be maintained while shortening the duration of postnephrectomy therapy. The current SIOP 2001 study is evaluating the ability to stratify patients for treatment based on postchemotherapy histologic findings.[58]

United Kingdom Children's Cancer Study Group

The UKCCSG has also conducted trials of children with Wilms' tumor.[111–113] The UK approach is to biopsy the tumor prior to treatment. They have noted a 12% incidence of non-Wilms' tumors in patients with the typical features of Wilms' tumor on imaging study.[114] Overall, there was 1% of benign lesions on biopsy, similar to rates found in SIOP studies.[108] The UKW1 and UKW2 studies evaluated the single-agent vincristine for treatment of stage I FH tumors.[111,112] The OS of 96% compares well with two-drug chemotherapy, but age >4 years was considered an adverse prognostic factor.[113]

Preoperative chemotherapy vs immediate nephrectomy

In summary, there is a different philosophical approach between the pediatric cancer cooperative groups. Both the NWTSG and SIOP tumor staging systems are designed to stratify patients into low-risk and high-risk groups. The goal is to select out high-risk patients for more intense therapy, while minimizing treatment and thus morbidity for low-risk patients. Both groups want to reduce the number of patients receiving irradiation and doxorubicin to avoid the late effects of treatment (see below). Currently, approximately 50% of SIOP patients are treated with an anthracycline and 17% undergo irradiation, whereas approximately 35% of NWTSG patients have received both therapies.[115,116] The NWTSG trials have relied on surgical and pathologic staging following immediate nephrectomy. Preoperative treatment can produce dramatic reduction in the size of the primary tumor, decreasing the morbidity of surgery (Figure 32.3).[117] However, the staging information obtained following prenephrectomy chemotherapy may inadequately define the risk of relapse.[107] The current SIOP and UK approach is using the histologic response of the tumor to preoperative therapy to decide postoperative treatment. The current strategy in North America will be to use biologic prognostic factors to stratify patients for therapy.

There are situations where preoperative chemotherapy is routinely recommended. This includes children with bilateral Wilms' tumors,[119,120] tumors inoper-

Figure 32.3 (*a*) Magnetic resonance imaging scan of a large inoperable Wilms' tumor. (*b*) After 6 weeks of chemotherapy, the same tumor has dramatically decreased in size. (Reproduced with permission from Richey et al.[118])

able at surgical exploration,[121] and tumor extension into IVC above the hepatic veins.[122–124] The latter two conditions are associated with an increased risk for surgical complications if primary nephrectomy is undertaken.[78] The rationale for preoperative chemotherapy in patients with bilateral tumors is to preserve renal parenchyma. This is important because renal failure is a significant risk in patients with bilateral disease.[125,126]

Vascular extension

For vena caval involvement below the level of the hepatic veins, the caval thrombus can be removed via cavotomy after proximal and distal vascular control is obtained. Generally, the thrombus will be free-floating, but if there is adherence of the thrombus to the caval wall, the thrombus can often be delivered with the passage of a Fogarty or Foley balloon catheter. If the thrombus extends above the level of the hepatic veins, preoperative chemotherapy can shrink the tumor and thrombus, facilitating complete removal.[122,127]

Inoperable tumor

A tumor should not be judged inoperable based on imaging studies alone. Preoperative imaging can overestimate local tumor extension and inoperability should only be determined on surgical exploration. It is also important to remember that the misdiagnosis rate of renal masses after assessment by diagnostic imaging is still 5%.[108,114] If the tumor is found to be unresectable, pretreatment with chemotherapy almost always reduces the bulk of the tumor, and renders it resectable[121,128] (see Figure 32.3). Patients who are staged by imaging studies alone are also at risk for understaging.[108] A patient determined to have an inoperable tumor should be considered stage III and treated accordingly.[121]

Repeat imaging is performed after 6 weeks of chemotherapy. Experience in SIOP has shown that maximal reduction in tumor volume occurs in the first 8 weeks.[108] After there has been adequate shrinkage of the tumor, definitive resection can be completed. A clinically good response (by imaging) is usually associated with a pathologically good response in terms of regressive histologic changes.[58,129] The converse is not always true. The distribution of histologic subtypes is different following preoperative chemotherapy compared with primary surgery, with differentiation of the tumor occurring after chemotherapy. Stromal and epithelial predominant tumors are found more often after preoperative chemotherapy.[58,129] These histologic subtypes may demonstrate a poor clinical response to therapy but have an excellent prognosis if the tumor is completely excised. Patients with progressive disease have a very poor prognosis and these patients will require treatment with a different chemotherapeutic regimen.[121]

Bilateral disease

Synchronous bilateral nephroblastoma occurs in about 5% of children with Wilms' tumor, with metachronous lesions developing in only 1% (Figure 32.4).[119,130,131] Therapy of children with bilateral Wilms' tumor (BWT) is directed towards preservation of renal parenchyma to avoid renal insufficiency. A review of NWTSG patients with BWT found that 9.1% of synchronous bilateral tumors and 18.8% of metachronous bilateral tumors have developed renal failure.[125] The most common etiology for renal failure was the need for bilateral nephrectomy for persistent or recurrent tumor in the remaining kidney after initial nephrectomy. NWTSG investigators noted that

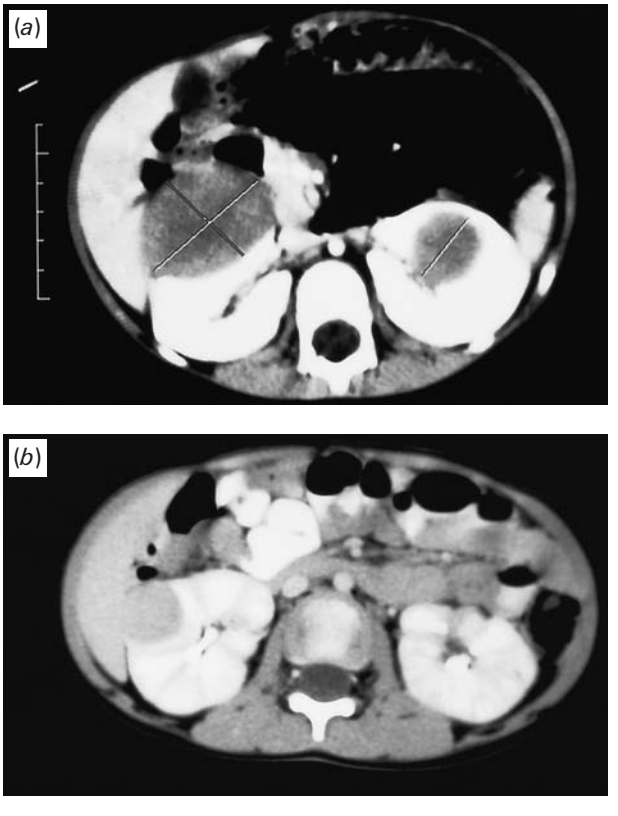

Figure 32.4 Computed tomography scan demonstrating bilateral Wilms' tumor: (*a*) before chemotherapy; (*b*) 6 weeks after chemotherapy, showing a marked reduction in the size of the masses.

nephrectomy could be avoided entirely in almost 50% of the group of patients undergoing initial biopsy followed by chemotherapy.

The initial management, therefore, is chemotherapy. Repeat imaging is done 6 weeks later to assess response of the tumors. Experience in SIOP has shown that maximal shrinkage occurs after 4–6 weeks of chemotherapy. As noted above, one cannot predict the histology of the tumor by response (on imaging) to the chemotherapy.[58,129] Differentiated tumors may show a poor clinical response to therapy, but have an excellent prognosis if the tumor is completely excised. Tumors with complete necrosis and predominantly regressive changes can also increase in size during therapy.[58] Tumors not responding to therapy require open biopsy to exclude anaplasia.

At the time of the second-look procedure, partial nephrectomy or wedge excision of the tumor should be considered, but only if complete tumor resection with negative margins can be obtained and part of either or both of the kidneys can be salvaged. If the tumors are not amenable to partial resections, patients with persistent viable tumor are then treated with a different chemotherapeutic regimen. The patient should be reassessed after an additional 12 weeks of chemotherapy to determine the feasibility of resection. If it appears that either or both of the kidneys can be salvaged, partial nephrectomies or wedge excisions of the tumors are performed. Radical nephrectomy is performed to remove the kidney with too extensive tumor involvement when only one of two can be preserved. Bilateral nephrectomies and dialysis may rarely be required when the tumors fail to respond to chemotherapy and radiation therapy. The recommended interval between successful completion of treatment of the Wilms' tumor and renal transplantation varies. Some clinicians advocate a waiting period of 2 years to ensure that the patient does not develop metastatic disease; others have found that a 1-year interval is sufficient.[132] SIOP investigators have noted that late relapses have occurred in patients with BWT more than 4 years post-treatment and recommended long-term follow-up.[131]

Partial nephrectomy in unilateral tumors

The success of renal preservation in BWT has prompted some centers to recommend renal sparing surgery for unilateral tumors.[133–135] They cite concern about the late occurrence of renal dysfunction in children who have undergone unilateral nephrectomy. There is both clinical and experimental evidence of hyperfiltration damage of remnant nephrons after a loss of renal mass. Following treatment for unilateral Wilms' tumor, some patients develop proteinuria and a decrease in creatinine clearance.[136,137] However, other investigators have failed to confirm these findings.[138,139] A review of NWTSG patients found that the incidence of renal failure in children with unilateral tumors is 0.25%.[125] Most of those patients had the Denys–Drash syndrome with intrinsic renal disease, which often progresses to end-stage disease even in the absence of tumor. More recently, other subgroups of patients at increased risk for renal insufficiency have been identified.[126] Patients with the WAGR syndrome have a markedly increased risk of renal failure. Breslow et al[126] found a 38% risk of renal failure that occurred at a median of 14 years from diagnosis. They also noted an increased risk for renal failure in children presenting with genitourinary anomalies and Wilms' tumor. In summary, the risk of developing renal failure following treatment appears to be quite low for most children with unilateral Wilms' tumor, although continued long-term follow-up of this cohort of children is necessary.

Screening of patients at an increased risk for the development of Wilms' tumor (e.g. BWS, hemihypertrophy, aniridia) will occasionally detect a small lesion inviting the possibility of a renal sparing procedure.[29] There is an increased incidence of metachronous Wilms' tumor development in patients undergoing unilateral nephrectomy if nephrogenic rests are found in the kidney adjacent to the tumor.[73] Children with BWS, hemihypertrophy, and aniridia do have an increased incidence of nephrogenic rests in comparison to patients with unilateral Wilms' tumor not associated with congenital anomalies.[69]

The majority of Wilms' tumors are too large for a partial nephrectomy at initial presentation. Therefore, pretreatment with chemotherapy is usually necessary if renal sparing surgery is to be considered.[133–135] Staging of the patient after chemotherapy could lead to inaccuracy, as discussed above. Some clinicians advocate enucleation of the tumor to allow parenchymal sparing procedures for even centrally located tumors where partial nephrectomy with a rim of renal tissue would be inadvisable.[134] However, anaplastic histology must be excluded before consideration of enucleation. The possible benefits of renal parenchymal conserving surgery must be evaluated against the potential risks of such procedures. Partial nephrectomy and enucleation increase the risk for positive surgical margins. A review of children with BWT enrolled in NWTS-4 found that the incidence of local recurrence was 7.5% following

partial nephrectomy and 14% after enucleation.[140] Although OS was comparable, patients with residual disease and recurrences required additional therapy to attain a similar outcome.

In summary, parenchymal sparing procedures for patients with unilateral Wilms' tumor are controversial. It seems reasonable to consider partial nephrectomy for patients with BWT, tumor in a solitary kidney, and renal insufficiency. For other children, this option should be approached with caution. The data reviewed above suggest a fivefold increase or 5% incidence of the development of metachronous Wilms' tumor in children in these high-risk categories. Does this risk justify the routine use of preoperative chemotherapy to facilitate partial nephrectomies in all patients with BWS, hemihypertrophy, or aniridia found to have unilateral tumors? As noted in the discussion above, there is a risk for undertreatment and potentially increased risk of local recurrence. These risks must be weighed against the possible benefit of decreasing the incidence of renal failure.

Late effects of treatment

Each therapeutic modality used in the management of Wilms' tumor can result in both acute and delayed toxicities. Numerous organ systems are subject to the late sequelae of anticancer therapy. Late effects of cancer therapy are predictable, based on treatment modalities used, age of patient at treatment, and time elapsed since therapy. Clinicians must now become familiar with the spectrum of problems that face these children as they grow into adulthood. Long-term follow-up of treatment-related complications has been an integral role of the NWTSG. One of the major objectives of the pediatric cancer cooperative groups has been to reduce the intensity of treatment in order to prevent or lower the morbidity of multimodal therapy without reducing efficacy.[141]

Children treated for Wilms' tumor are at increased risk for second malignant neoplasms (SMNs). NWTSG investigators reported that 15 years after initial (Wilms' tumor) diagnosis, the cumulative incidence of an SMN is 1.6% and increasing steadily.[142] This is more than eight times the expected incidence. The risk of developing leukemia or lymphoma is greatest in the first 8 years after treatment. The risk of developing a solid tumor continues to increase over time. Most tumors occur in previously irradiated areas, but prior treatment for relapse, and use of DOX were also associated with an increased incidence of SMNs.

Congestive heart failure is a known complication of treatment with an anthracycline.[143] The frequency is directly proportional to the cumulative dose of DOX received. In addition to the acute cardiotoxicity, reports are surfacing of cardiac failure up to 20 years after treatment.[144] In a preliminary review of patients entered on NWTS-1, -2, and -3, the frequency of congestive heart failure was 1.7% among DOX-treated patients.[145] The risk was increased if the patient received whole lung irradiation. In light of these findings, all children who undergo treatment with these modalities should undergo periodic re-evaluation.

Growth disturbances are known complications of cancer therapy in children. Spinal irradiation can result in severe reduction in spinal growth.[146] Similarly, chemotherapeutic agents can have a direct effect on chondrocytes, resulting in resistance to endogenous growth hormone and subsequent growth impairment.[147] Hogeboom et al studied the impact of treatment on stature in Wilms' tumor patients.[148] They concluded that while reductions in stature directly correlated to total radiation dose and age at treatment, currently recommended radiation doses should not result in a clinically significant impact.

Damage to reproductive systems can lead to problems with hormonal dysfunction and/or infertility. Gonadal radiation in males can result in temporary azoospermia and hyogonadism.[149] The effect on the testis is dose related, and the prepubertal germ cells also appear to be radiosensitive. In a follow-up of 10 men treated for Wilms' tumor in childhood, oligospermia or azoospermia was found in 8.[150] The Leydig cells are more radioresistant than the germ cells, but higher doses can produce damage resulting in inadequate production of testosterone. This can result in delayed sexual maturation.

Chemotherapeutic agents can interfere with testicular function, particularly alkylating agents. Acute toxicity with germ cell depletion occurs in all age groups. Some long-term studies suggested that prepubertal testes are resistant to chronic toxicity.[151] However, recent studies have indicated that prepubertal testes are not protected from chemotherapy-induced damage.[152,153] One report found that 12 of 19 prepubertal males treated for a variety of solid tumors were sterile as a result of treatment.[153]

Female Wilms' tumor patients who received abdominal radiation have a 12% incidence of ovarian failure.[154] Of 16 women who received whole abdominal irradiation, all had evidence of ovarian failure and 75% were amenorrheic.[155] As with the testis, the effect on the ovaries is dose dependent. Chemotherapy-

induced damage to the ovaries is most often associated with alkylating agents. A decrease in the number of follicles is seen in prepubertal girls treated with chemotherapy.[156] Premature menopause is a common complication of female childhood cancer survivors.[157] It is usually associated with radiation therapy and/or treatment with alkylating agents. Byrne et al demonstrated that women receiving alkylating agents were 9.2 times more likely to enter premature menopause.[157] Although further studies are needed to assess the extent of the problem, it appears prudent to counsel survivors at risk that a delay in first pregnancy may preclude having children.[158] In the future, cryopreservation and reimplantation of oocytes may be a viable alternative for these patients.

Several studies have addressed the risk of pregnancy in survivors after childhood cancer therapy. As noted above, girls with Wilms' tumor appear to have a higher incidence of Müllerian anomalies, causing some authors to suggest postpubertal level 2 ultrasound evaluation to detect these abnormalities prior to pregnancy.[21] Women with prior abdominal radiation have the greatest potential for adverse pregnancy outcomes. In a study of patients treated for Wilms' tumor, an adverse outcome occurred in 3% among non-irradiated women compared with 30% of women who received abdominal irradiation.[159] Perinatal mortality rates are higher, and infants are more likely to have low birth weights. The potential mutagenic effects of anticancer therapy are of concern. Most studies have found no increase in the incidence of congenital anomalies and no cases of Wilms' tumor in the offspring of survivors.[159,160]

Most children treated for Wilms' tumor undergo unilateral nephrectomy as part of the initial treatment. As noted above, there is risk of dysfunction of the solitary remaining kidney. Impairment of renal function may be related to irradiation, administration of nephrotoxic chemotherapeutic agents, or hyperfiltration of the remaining nephrons. Initially, there is compensatory hypertrophy that develops in this kidney.[161,162] The data are conflicting regarding renal compensatory hypertrophy in patients who receive whole abdominal irradiation. Walker et al found no difference in renal lengths between patients treated with chemotherapy and radiation vs chemotherapy alone.[161] However, a more recent report used ultrasound to calculate renal lengths and found that patients receiving radiation had poor compensatory growth.[162]

The kidney is sensitive to the effects of radiation. Radiation doses to the kidney should be limited to 12–15 Gy. Mitus and colleagues correlated functional impairment with the renal radiation dose in a review of 100 children treated for Wilms' tumor.[163] The incidence of impaired creatinine clearance was significantly greater for children receiving >12 Gy to the remaining kidney and all cases of overt renal failure occurred in patients who had received >23 Gy. Clinical signs of radiation nephritis may occur very acutely or begin months or years after therapy is discontinued.[163] Direct radiation nephrotoxicity is the usual cause, with injury to the intrarenal vasculature. Nephrotoxicity related to chemotherapy is well documented. Studies in children have demonstrated that alkylating agents in particular are associated with renal tubular dysfunction related to drug metabolites.[164] Unfortunately, Mesna has not been protective against these effects. A recent study by Bardi et al has suggested that high-risk Wilms' patients receiving agents such as cyclophosphamide may be at risk for early, subclinical, renal dysfunction, as evidenced by elevated levels of cystatin C, a measure of glomerular function, and elevated *N*-acetyl-β-D-glucosaminidase along with microalbuminuria.[165] The latter are both indicators of proximal tubular dysfunction. The long-term significance of these findings remains to be determined.

Other renal tumors of childhood

Cystic partially differentiated nephroblastoma

Cysts are common in Wilms' tumor and range in size from microscopic to several centimeters in diameter. Tumors composed of only cysts with immature nephrogenic elements and blastema within the delicate septa are designated cystic partially differentiated nephroblastoma. The majority of these lesions occur in the first year of life.[166] These lesions are indistinguishable radiographically from solitary multilocular cyst described below. Surgery is curative in almost all patients, with recurrence the result of incomplete resection.[167,168]

Multilocular cystic nephroma

Multilocular cystic nephroma, also known as solitary multilocular cyst, is an uncommon, benign renal tumor with a bimodal incidence. This tumor is distinguished by the finding of only mature cell types within the septa of the cyst wall. Fifty percent of the multilocular cysts reported in the literature have been

found in children younger than 4 years; boys predominate in a ratio of 2:1. The second peak incidence occurs in adults, and, unlike the pediatric cases, are usually in women.[169]

Cystic nephromas are commonly found incidentally on radiographic studies, but may present as an abdominal mass found on routine physical examination. Whereas the majority of cases of multilocular cystic renal disease have been unilateral, there are rare reports of bilateral cases.[170] The gross appearance of the tumor is its most distinguishing feature. The cut surfaces reveal a well-circumscribed multilocular tumor composed of cysts ranging from several millimeters to several centimeters in greatest diameter. The tumor is well encapsulated, compressing the surrounding renal parenchyma.

Multilocular cystic nephroma is a benign lesion which is cured by nephrectomy. Recurrence has occurred following incomplete excision by partial nephrectomy. If partial nephrectomy is considered, frozen section is indicated to exclude cystic, partially differentiated nephroblastoma.[166]

Congenital mesoblastic nephroma

Congenital mesoblastic nephroma (CMN) is the most common renal tumor in infants, with a mean age at diagnosis of 3.5 months.[171] The typical presentation is a newborn with an abdominal mass, but in recent years a number of cases have been recognized prenatally, with polyhydramnios a frequent prenatal finding.[172,173] Tumor induction is postulated to occur at a time when the multipotent blastema is predominately stromagenic.[174] The neoplasm is distinct from Wilms' tumor and has three histologic subtypes: classic, cellular, and mixed (showing areas of both classical and cellular).The classic subtype, 24% of cases, is characterized by interlacing sheets of bland spindle cells. Classic CMN resembles infantile fibromatosis. The cellular variant, 66% of cases, has a solid sheet-like growth pattern and cells with little cytoplasm and frequent mitoses.[175–177] The cellular variant is virtually identical histologically to congenital fibrosarcoma. Molecular studies have found a similar translocation in both tumors that fuses the *ETV6* (*TEL*) gene from chromosome 12p13 with the chromosome 15q25 neurotrophin-3 receptor gene, *NTRK3*.[178]

Imaging studies cannot reliably distinguish CMN from other renal mass lesions. Abdominal CT shows a heterogeneous solid mass arising from the kidney (Figure 32.5). Complete excision is curative for most

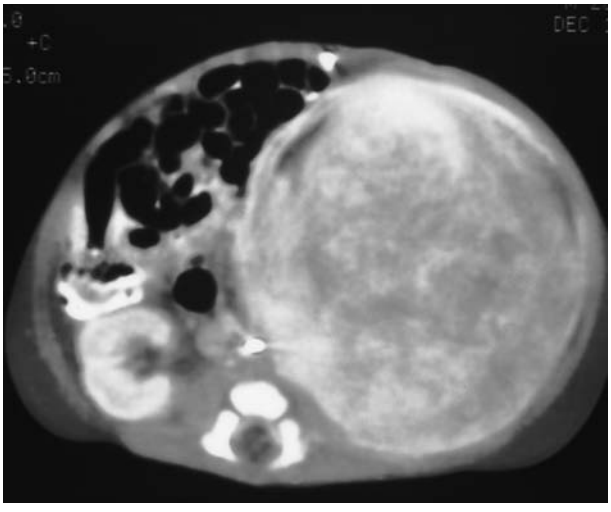

Figure 32.5 Computed tomography scan of an infant with congenital mesoblastic nephroma.

patients with CMN.[171] Local recurrence and metastasis can occur, particularly with the cellular variant of CMN.[175,176] The pathology specimen will often identify extension of tumor into the hilar or perirenal soft tissue; therefore, complete surgical resection is important.[177] The risk of recurrence is thought to be less in children under 3 months of age at diagnosis, but metastases have been reported in a few infants.[179] Neither chemotherapy nor radiation therapy is routinely recommended,[171] but consideration for adjuvant treatment should be given to patients with cellular variants that are incompletely resected.[176] There are reports demonstrating response of both inoperable and recurrent tumors to chemotherapy.[180,181]

Clear cell sarcoma of the kidney

This tumor is also known as the 'bone-metastasizing renal tumour of childhood' because of its predilection for these sites.[59,182] There are also an increased number of brain metastases with this entity.[183] CCSK accounts for 3% of renal tumors reported to the NWTSG. Unlike anaplastic Wilms' tumor, even stage I CCSK lesions are associated with increased rates of relapse. There are no reports of children with bilateral CCSK. Studies have demonstrated that the use of DOX is associated with a significant improvement in outcome for these children.[82,184] Patients with CCSK were treated on NWTS-5 with a regimen combining VCR, DOX, cyclophosphamide, and etoposide in an attempt to further improve the survival of this high-

risk group, but results of that trial are pending. All patients with CCSK require irradiation to the tumor bed.

Rhabdoid tumor of the kidney

RTK was first identified by NWTSG pathologists in 1978.[59] This is a highly malignant tumor of the kidney and accounts for 2% of renal tumors registered to the NWTSG.[82,89] The tumor derives its name from the resemblance to rhabdomyoblasts, but it is not derived from myogenic cells; the cell of origin is unknown. This tumor is typically seen in infants and very young children, with a median age of 13 months. Infants with RTK often have concurrent brain tumors. It is difficult to ascertain if these are metastases or two distinct primary tumors.[185] Recent studies suggest that there is a common genetic basis for renal and extrarenal rhabdoid tumors in infants.[186] There is a deletion or mutation in the tumor suppressor gene *INI-1* on chromosome 22 that predisposes to the development of this tumor. Staining for the products of the *INI-1* gene can be useful, as RTK is consistently negative.[187] The prognosis of patients with rhabdoid tumor remains dismal with conventional chemotherapeutic regimens, with over 80% of children dying within 1 year of diagnosis.[188] In NWTS-5, children with all stages of rhabdoid tumor were treated with carboplatin, cyclophosphamide, and etoposide; they also received abdominal irradiation, but results of that trial are pending.

Renal cell carcinoma

Only 5% of renal cell carcinomas occur in children.[189] These patients generally present after age 5 years, and it is the most common renal malignancy in the second decade of life.[190] Survival of children with renal cell carcinoma is dependent on the ability to completely resect the tumor. Raney et al found that all children with stage I lesions survived;[191] OS was about 50%. Age is also a prognostic factor, with improved survival in children younger than 11 years.[191] A recent report suggested that local lymph node involvement does not predict a poor outcome compared with adult renal cell carcinoma.[192] Renal cell carcinomas in children also differ in their morphology and molecular characterization. There is a higher percentage of *TFE3* (transcription factor micro E3 binding protein) 'translocation' carcinomas and 'unclassified' carcinomas in the first two decades of life.[193] There is also a lower frequency of clear cell carcinomas and *VHL* (von Hippel–Lindau gene) alterations compared with adults. These tumors do not appear responsive to chemotherapy or radiation therapy.
